Abstract

Context: Anemia and decreasing levels of hemoglobin (Hb) have previously been linked to increased fracture risk, but the added value to FRAX, the most utilized fracture prediction tool worldwide, is unknown.

Objective: To investigate the association between anemia, Hb levels, bone microstructure, and risk of incident fracture and to evaluate whether Hb levels improve fracture risk prediction in addition to FRAX clinical risk factors (CRFs).

Methods: A total of 2778 community-dwelling women, aged 75-80 years, and part of a prospective population-based cohort study in Sweden were included. At baseline, information on anthropometrics, CRFs, and falls was gathered, blood samples were collected, and skeletal characteristics were investigated using dual-energy x-ray absorptiometry and high-resolution peripheral quantitative computed tomography. At the end of follow-up, incident fractures were retrieved from a regional x-ray archive.

Results: The median follow-up time was 6.4 years. Low Hb was associated with worse total hip and femoral neck bone mineral density (BMD), and lower tibia cortical and total volumetric BMD, and anemia was associated with increased risk of major osteoporotic fracture (MOF; hazard ratio 2.04; 95% CI 1.58-2.64). Similar results were obtained for hip fracture and any fracture, also when adjusting for CRFs. The ratio between 10-year fracture probabilities of MOF assessed in models with Hb levels included and not included ranged from 1.2 to 0.7 at the 10th and 90th percentile of Hb, respectively.

Conclusion: Anemia and decreasing levels of Hb are associated with lower cortical BMD and incident fracture in older women. Considering Hb levels may improve the clinical evaluation of patients with osteoporosis and the assessment of fracture risk.

Key Words: fracture risk, older risk, anemia, hemoglobin level, fracture risk assessment

Abbreviations: BMD, bone mineral density; BMI, body mass index; CRF, clinical risk factor; CV, coefficient of variation; DXA, dual-energy x-ray absorptiometry; eGFR, estimated glomerular filtration rate; FN BMD, femoral neck bone mineral density; Hb, hemoglobin; HR-pQCT, high-resolution peripheral quantitative computed tomography; MOF, major osteoporotic fracture.

Anemia is a common condition associated with morbidity and mortality, independently and through an array of comorbidities (1). It is characterized by decreased levels of red blood cells and is currently defined by the World Health Organization (2, 3) as hemoglobin (Hb) levels of <12 g/dL for women and <13 g/dL for men. Interestingly, previous studies have shown an increased risk of fracture with the prevalence of anemia and decreased levels of Hb in both men and women (1, 3-10), associations supported by known interactions between processes of bone metabolism and...
hematopoiesis (11-14). Although the underlying mechanism behind anemia and fracture risk remains to be resolved, anemia has been associated with several risk factors including low bone mineral density (BMD), cardiovascular disease, low general self-rated health status, impaired cognition, low physical function, sarcopenia, and falls (1, 5, 15-19). Additionally, the risk has been particularly apparent in men, with studies on postmenopausal women showing inconsistent results and generally lower risk increases in women, as shown in a recent meta-analysis (16). The cause for this sex-specific difference remains unclear.

Over the last few decades, significant improvements in osteoporosis diagnostics and fracture risk assessment have been accomplished, as well as the development of new and more effective osteoporosis medications (20). However, due to factors such as an aging demographic and urbanization, the incidence of osteoporotic fracture is projected to increase (21). The fracture risk assessment tool, FRAX, combines age, sex, and body mass index (BMI) with a set of clinical risk factors (CRFs) and an optional femoral neck bone mineral density (FN BMD) to estimate the 10-year probabilities of hip and major osteoporotic fractures (MOF; distal forearm, proximal humerus, clinical spine, and hip) (22, 23). Since its introduction in 2008, it has been incorporated into more than 80 guidelines for osteoporosis management and is currently the most used fracture prediction tool worldwide (22, 24). Although the FRAX tool considers many CRFs and has numerous advantages, it lacks several potentially important input variables regarding other known risk factors for fracture (22).

Given the previous findings, the primary aim of this study was to investigate further the association between Hb levels and risk of incident fracture in older women and to evaluate the contributing effect of Hb levels on 10-year fracture probabilities as calculated by the FRAX tool. Secondary aims were to analyze the associations between anemia and levels of Hb with variables of BMD and bone microstructure derived from dual-energy x-ray absorptiometry (DXA) and high-resolution peripheral quantitative computed tomography (HR-pQCT).

Materials and Methods

The study subjects were part of the Sahlgrenska University Hospital Prospective Evaluation of Risk of Bone Fractures (SUPERB) study, and inclusion, cohort characteristics, and the methods used have been described in detail in previous publications (25-29).

Subjects

Postmenopausal women aged 75-80 years old at baseline and living in the Gothenburg area, Sweden were randomly selected from the Swedish national population registry between March 2013 and May 2016. Invitations to participate were sent by letter and telephone to a total of 6832 community-dwelling women. The exclusion criteria were not being able to communicate in Swedish, having had bilateral hip replacement, and not being ambulant with or without walking aids. A total of 3028 women were included in the SUPERB study following exclusion of 436 women and 3368 who declined to participate. Prior to examinations, the participants signed an informed consent form, and the study was approved by the regional Ethics Review Board in Gothenburg, Sweden.

Anthropometrics and Questionnaires

Height (to the nearest 1 mm) and weight (to the nearest 0.1 kg) were measured using the same standardized equipment for the entire cohort, and mean values were used in the analyses. Information regarding the CRFs was obtained through questionnaires and included if the participant had a previous fracture, had a parent with a prior hip fracture, currently smoked tobacco, had been exposed to oral glucocorticoids (of doses corresponding to ≥5 mg of prednisolone for over 3 months in total), and if they had been diagnosed with rheumatoid arthritis. Secondary osteoporosis was defined as having either of diabetes mellitus, hyperthyroidism, chronic liver disease, inflammatory bowel disorder, or premature menopause (<45 years old), and was assessed by asking if the participant had been told by a doctor if they had any of the conditions (yes/no) and at which age menstruations ended. Excessive alcohol intake was defined as 3 or more alcoholic drinks per day. Falls were assessed by asking (yes/no) if the participant had experienced a fall during the last 12 months. The FRAX 10-year probabilities for hip and MOF were calculated with and without FN BMD, using the Sweden-specific model. Previous osteoporosis treatment was assessed by asking (yes/no) if the participant had ever used bisphosphonates, zoledronic acid, strontium, teriparatide, or denosumab and if yes, between which dates.

Blood Analyses

Blood samples were collected from all participants at the baseline visit. Plasma and serum samples were immediately stored at −80 °C until further analysis. Hb was analyzed at the Department of Clinical Chemistry (accredited testing laboratory, Swedac no. 1240), Sahlgrenska University Hospital, Gothenburg, Sweden, using a CN-free Hb method using the ADVIA 2120i system (Siemens Healthcare Gmbh, Erlangen, Germany) with an analytical range of 0-22.5 g/dL and total coefficients of variation (CVs) of <1.5% at 3 different levels of Hb. Serum albumin and creatinine were analyzed at the Department of Clinical Chemistry (accredited testing laboratory, Swedac no. 1342), Linköping University Hospital, Sweden, and all samples were assayed with reagents from the same batch on a cobas c 701 instrument (Roche Diagnostics Scandinavia AB, Gothenburg, Sweden). Serum albumin was measured by immunoturbidimetry with an analytical range of 3.0 to 101 g/L and total CVs of ≤2% at different albumin levels. Serum creatinine was measured enzymatically with an analytical range of 5 to 2700 µmol/L and total CVs of ≤5% at 2 different creatinine levels. Estimated glomerular filtration rate (eGFR) was calculated using the Lund-Malmö revised (LMR) equation (30).

Dual-Energy X-Ray Absorptiometry

The areal bone mineral density (aBMD) was assessed using DXA (Hologic Discovery A, MA, USA). The aBMD (g/cm²) was analyzed at the nondominant radius, lumbar spine (L1-L4, excluding fractured vertebrae and/or vertebrae with osteosynthesis material), total hip, and femoral neck. The CVs were 3.1% for the radius, 0.68% for the lumbar spine, 0.83% for the total hip, and 1.3% for the femoral neck.
High-Resolution Peripheral Quantitative Computed Tomography
HR-pQCT (XtremeCT, Scanco Medical AG, Switzerland) was used to assess bone microstructure and volumetric bone mineral density (vBMD). The ipsilateral tibia to the nondominant hand (the contralateral tibia in case of a previous fracture) was analyzed at 2 sites. A reference line was established at the distal tibia articular plateau. The distal site was at 14% of the tibia length from the reference line, the ultradistal site was at a standard 22.5 mm from the reference line. A total of 110 images were taken over 9.02 mm in a proximal direction at each site and were applied to create 3D models. The parameters calculated were total, cortical, and trabecular cross-sectional areas (mm²) and vBMD (mg/cm²), trabecular separation (mm) and thickness (mm), periosteal circumference (mm), cortical porosity (%), and trabecular bone volume fraction (trabecular bone volume/total bone volume, %). The quality of the images was graded on a scale of 1 to 5, as recommended by the manufacturer, and images with low quality (grade 4-5) at either site were excluded from further analysis. A total of 112 women with images of a low quality were excluded from the analysis of HR-pQCT variables.

Incident Fracture Evaluation
Evidence of incident fractures in the form of x-ray images and/ or x-ray reports were retrieved from medical records or from the regional x-ray archives, including Gothenburg and surrounding municipalities. All incident fractures in the regional archive were recorded at the end of follow-up and reviewed by a research nurse and an experienced orthopedic surgeon. The incident fractures were categorized as either hip, MOF, or any fracture (including all fracture types, except for fractures of the fingers, toes, and skull). No regular x-ray monitoring was conducted, and only incident clinical vertebral fractures identified on examinations with a fracture inquiry were included. Deaths and date of deaths were identified using the regional database Västfolket.

Statistical Analyses
Continuous variables were assessed for normality using histograms and tests of skew and kurtosis. Normal distributions were approximated using log transformation for positively skewed variables. The associations between investigated outcome variables and anemia status were analyzed using independent samples t-tests, Mann–Whitney U tests, chi-squared tests, and Fisher’s exact tests. The associations to Hb level were assessed using Pearson and Spearman correlation and adjusted linear regression models (adjusted for age, height, and weight). The associations between the risk of incident fractures, anemia, and Hb level to DXA and HR-pQCT variables were analyzed using independent samples t-tests, Mann–Whitney U tests, chi-squared tests, and tests of skew and kurtosis. Normal distributions were approximated using log transformation for positively skewed variables. The quality of the images was graded on a scale of 1 to 5, as recommended by the manufacturer, and images with low quality (grade 4-5) at either site were excluded from further analysis. A total of 112 women with images of a low quality were excluded from the analysis of HR-pQCT variables.

Results
A total of 2778 (91.7%) women had complete data on Hb, CRFs, and FN BMD and were included in the analysis. Of these, the mean Hb was 13.5 g/dL, and 185 women (6.7%) were anemic (Table 1).

Baseline Characteristics and Associations With Anemia Status and Hemoglobin Level
The cohort baseline characteristics are presented in Table 1. Women with anemia had higher relative frequencies of rheumatoid arthritis and secondary osteoporosis, experienced falls in the last 12 months, and had higher FRAX probabilities for hip and MOF when assessed with FN BMD. The Hb level was positively correlated with age, height, weight, and albumin and inversely associated with creatinine and the FRAX 10-year probabilities for hip and MOF, both assessed with and without FN BMD. Hb levels were higher in women who currently smoked but lower in women with a previous fracture, exposed to oral glucocorticoids, had rheumatoid arthritis, and experienced falls (Table 1).
There were no significant differences in the mean Hb levels or weight, and height. No associations between Hb levels and FN BMD and total hip BMD following adjustments for age, included and excluded women based on image quality grading (adjusted for age, weight, and height) associations in Table 2 and HR-pQCT variables are presented as crude and adjusted. The relationship between anemia status and Hb levels to DXA variables remained after adjustment (Table 2). At the distal tibia site following adjustment, women with anemia had higher total area, greater periosteal circumference, and higher cortical porosity, and the Hb level was inversely associated with these variables (Table 2). Also at the distal site, anemia was associated with lower total and cortical vBMD and the Hb level was positively associated with cortical vBMD (Table 2). At the ultradistal site following adjustment, women with anemia had a higher total area and periosteal circumference and the Hb level was inversely associated with the same variables (Table 2). Also at the ultradistal site, anemia was associated with a lower cortical area, and total and cortical vBMD, and Hb levels were positively associated with total and cortical vBMD and with trabecular thickness (Table 2).

Baseline characteristics are presented as mean ± SD for continuous variables and number of subjects and group percentages in parentheses for categorical variables. Independent samples t-tests and chi-squared tests were used to evaluate differences in means and frequencies across groups of anemia status. Pearson correlation and independent samples t-tests were used to analyze the associations with Hb levels. Statistically significant associations are shown in bold. Abbreviations: BMD, bone mineral density; Hb, hemoglobin; MOF, major osteoporotic fracture. ⁵Median ± interquartile range, Mann–Whitney U test, and Spearman correlation. ⁶Fisher’s exact test. ⁷n = 2777. ⁸n = 2752.

### Association of Hemoglobin Levels to Secondary Osteoporosis

Hb levels were lower in women with diabetes mellitus and inflammatory bowel disease, although the latter was only borderline statistically significant. There was no statistical difference in Hb levels between women with hyperthyroidism, premature menopause, or chronic liver disease compared with controls (Table 1).

### DXA and HR-pQCT—Associations With Anemia Status and Hemoglobin Level

The relationship between anemia status and Hb levels to DXA and HR-pQCT variables are presented as crude and adjusted (adjusted for age, weight, and height) associations in Table 2. There were no significant differences in the mean Hb levels or proportions of women between anemia of included and excluded women based on image quality grading (data not shown). Anemia was negatively associated with FN BMD and total hip BMD following adjustments for age, weight, and height. No associations between Hb levels and DXA variables remained after adjustment (Table 2). The Association of Anemia and Hemoglobin Level to Risk of Incident Fracture and Death

The associations between anemia and Hb level with the risk of incident fractures are presented in Table 3. The median follow-up time was 6.4 years (interquartile range 5.7-7.3)

The association of anemia status and Hb level to DXA and HR-pQCT variables are presented as crude and adjusted values. Crude values are evaluated using independent t-tests and Pearson correlation for anemia status and Hb level, respectively. The adjusted beta coefficients are derived from linear regression models adjusted for age, weight, and height. The beta coefficients shown are SD change in dependent variable with the prevalence of anemia and per SD increase in Hb level (standardized beta). Statistically significant associations are shown in bold.

Abbreviations: aBMD, areal bone mineral density; BV/TV, trabecular bone volume/total bone volume; DXA, dual-energy x-ray absorptiometry; Hb, hemoglobin; HR-pQCT, high-resolution peripheral quantitative computed tomography; vBMD, volumetric bone mineral density.

during which 148 (5.3%) hip fractures, 601 (21.6%) MOFs, 734 (26.4%) any fractures, and 344 (12.4%) deaths occurred. In Cox proportional hazards models adjusted for age, height, weight, FRAX CRFs, and FN BMD, the prevalence of anemia was associated with an increased risk for hip fracture (hazard ratio [HR] 1.75, 95% CI 1.06-2.90), MOF (HR 1.85, 1.43-2.41), and any fracture (HR 1.80, 1.41-2.28; Table 3). In models with identical adjustments but per SD decrease in Hb levels, there was an increased risk for hip fracture (HR 1.19, 1.01-1.39), MOF (HR 1.22, 1.12-1.32), and any fracture (HR 1.23, 1.14-1.33; Table 3). Similar results were obtained when considering death as a competing risk in addition to all adjustments in models by Fine and Gray (Table 3). The HRs did not materially change with the addition of falls (1 or more during the last 12 months) as a covariate to fully adjusted models (HR per SD decrease in Hb: hip fracture 1.18, 1.00-1.38; MOF 1.21, 1.12-1.31; and any fracture 1.23, 1.14-1.32). Similarly, the fracture risks were largely unaffected by adding eGFR as an additional adjustment to already fully adjusted models (HR per SD decrease in Hb: hip fracture 1.18, 1.00-1.38; MOF 1.22, 1.12-1.32; and any fracture 1.24, 1.15-1.33). Likewise, the fracture risks were largely unaffected by adding previous osteoporosis treatment as an additional adjustment to already fully adjusted models (HR per SD decrease in Hb: hip fracture 1.18, 1.01-1.39; MOF 1.21, 1.12-1.31; and any fracture 1.23, 1.14-1.32). There were minor differences in fracture risks when adding serum albumin as a covariate to already fully
adjusted models (HR per SD decrease in Hb: hip fracture 1.15, 0.97-1.35; MOF 1.18, 1.09-1.29; and any fracture 1.21, 1.12-1.30). Similar results were obtained when adding diabetes mellitus as a covariate to fully adjusted models (HR per SD decrease in Hb: hip fracture 1.18, 1.01-1.39; MOF 1.21, 1.11-1.31; and any fracture 1.23, 1.14-1.32). The prevalence of anemia was associated with an increased risk of death (HR 2.06, 1.49-2.86) and similarly decreasing levels of Hb (HR per SD decrease 1.12, 1.01-1.25; Table 3). The associations remained largely unaffected following adjustments (adjusted for age, height, weight, and FRAX CRFs; Table 3).

The adjusted spline regression curves for hip and MOF, and any fracture according to Hb levels revealed no apparent non-linear associations (Fig. 1). The relationship between the incidence rate of death and Hb levels had its nadir at approximately median Hb 13.6 g/dL from which it increased with increasing levels of Hb (Fig. 1).

### Hb Levels and Fracture Probabilities
For a 75-year-old woman with BMI 26 kg/m², no CRFs, and without considering FN BMD, the 10-year probability of MOF with Hb included in the model ranged from 25.9% to 14.8% at the 10th and 90th percentile of Hb, respectively (Fig. 2A and Table 4). This corresponded to a ratio of 1.2 and 0.7 at the 10th and 90th percentile of Hb, respectively, when comparing the 10-year probability of MOF assessed in models with Hb included and not included. Similar results were obtained for an 80-year-old woman under the same conditions (Table 4). The relationship between the ratio of probabilities calculated with and without Hb to the level of Hb is illustrated in Fig. 2B.

### Discussion
In this population-based cohort of older Swedish women, we found an increased risk of fracture with both the prevalence of anemia and decreasing levels of Hb. The increased risk was independent of FRAX CRFs and FN BMD and when considering death as a competing event. Considering Hb levels had a substantial effect on 10-year fracture probabilities where the probability was underestimated in patients with low Hb levels and overestimated in patients with high Hb levels. Anemia and low Hb levels were also associated with BMD at the femoral neck and total hip, as well as with cortical vBMD and porosity of the tibia, indicating that bone fragility with low Hb is due to a primarily affected cortical bone.
outcomes, and applying these cut-offs to fracture risk assessment seems to have no basis (37).

Our results indicate that there is a divergence between the risk of fracture and the risk of death as the incidence rate of death seems to increase above the median Hb level. Primary erythrocytosis is well known to be associated with an increased risk of thrombosis and mortality, although not very common with a prevalence of approximately 0.4% in women and thus unlikely to entirely explain this discrepancy (38). However, we speculate that the more common type, secondary erythrocytosis, caused by factors such as general tissue hypoxia (smoking, obstructive sleep apnea, and hypoxic lung disease, etc.) and local renal hypoxia (renal artery stenosis and hydronephrosis, etc.) is likely to, by proxy of its underlying etiologies, explain some of the increased incidence of death (38). Additionally, it seems intuitive that the increased risk of death would act as an increasing competing risk to the fracture risk analysis, explaining lower incidence of fracture. However, this was analyzed in the competing risk analysis using the Fine and Gray method, showing little or no difference in magnitude or significance.

When analyzing skeletal characteristics with traditional DXA methodology, we found that women with anemia had lower FN BMD and total hip aBMD but without any associations with Hb levels. In previously published studies, there has been no clear consensus regarding the association with aBMD in cross-sectional analyses, instead stronger associations with aBMD loss have been found (11, 12, 19, 39). There is very limited research on the associations between HR-pQCT variables and anemia, with only a few studies on subjects with specific conditions such as thalassemia (40).

Our study is the first to analyze the associations between bone variables assessed by HR-pQCT and anemia and/or Hb level in a population-based cohort setting. We found associations between anemia, Hb level, and predominantly cortical bone variables, such as cortical area, cortical vBMD, and cortical porosity. We hypothesize that this association could be due to cortical bone, as, compared with trabecular bone, is more dependent on Hb levels for a sufficient supply of oxygen while the increased vascularization of trabecular bone renders it more independent of Hb levels. This may be a contributing mechanism through which Hb levels affect fracture risk. The lack of associations with traditional DXA-derived BMD could be the result of DXA BMD relying on cortical and trabecular BMD, as well as bone size, making it difficult to identify any factor that is predominantly associated with any of these specific traits. In support of our results, a study analyzing variables derived from pQCT of tibia in relation to anemia and Hb levels found that anemia was

Figure 1. The relationship between hemoglobin level (Hb) and incidence rates for fracture and death. Spline Poisson regression curves (continuous lines) with 95% CI (dashed lines) adjusted for age, height, and weight are shown for hip fracture (A), major osteoporotic fracture (MOF) (B), any fracture (C), and death (D).
negatively associated with total and cortical vBMD, and Hb levels were positively associated with the same variables in addition to trabecular vBMD (18).

The results from the present study have several clinical implications. First, our results indicate that anemia, or more appropriately Hb levels, are significantly and independently associated with fracture risk and thus should be considered as an additional factor when assessing fracture risk in older women. Our results demonstrate that Hb levels contributed to the 10-year probabilities of MOF as calculated by methods similar to those used in the FRAX algorithm. However, it should be emphasized that additional studies confirming our results in patients with a wider range of age and other settings are necessary prior to any general recommendations regarding the use of Hb levels in adjusting 10-year fracture probabilities. If these findings are confirmed, Hb-derived multipliers can be used to calculate Hb-adjusted FRAX 10-year probabilities, as previously proposed for adjustment of FRAX probabilities for oral glucocorticoid use, recent fracture, and previous falls (41-43). Analyzing the Hb concentration requires few resources, is part of a standard clinical evaluation, and it is likely that many of the individuals being assessed in terms of fracture risk already have a recent Hb result available. Thus, incorporating Hb levels into fracture risk prediction is likely feasible from a resource point of view.

Among the strengths of this study is the size of the cohort, the extensive characterization of participants, with both HRpQCT and DXA, access to data for a large number of CRFs, and potential confounders, as well as high-quality fracture outcome data, using x-ray verification of fractures.

The present study also has limitations, including the cross-sectional design relying on single measurements of Hb and BMD, not allowing inferences of causality, or reversibility of risk due to Hb levels. Not all participating women in the SUPERB cohort were included in the analyses, due to missing data on Hb levels or due to insufficient image quality of HRpQCT images, which could have affected the results. Unfortunately, none of the collected data made it possible to make any inferences about different etiologies of anemia and fracture risk. Additionally, the study is limited in that no data on hematological disorders were known.

In conclusion, anemia and decreasing levels of Hb are associated with lower BMD, worse cortical bone traits, and incident fracture, independently of FRAX CRFs and BMD in older women. Considering Hb levels may improve the clinical evaluation of patients with osteoporosis and assessment of fracture risk.

The 10-year probabilities for MOF are derived from extended Poisson regression models extrapolated to 10 years. The probabilities presented are for women aged 75 and 80 years, with cohort mean BMI (26 kg/m²), no CRFs and without considering FN BMD. The 10-year probabilities of MOF, when Hb is included, are shown for the 10th, 50th and 90th percentiles of Hb. The fourth column presents the MOF probability ratios calculated with Hb included to Hb not included. The fifth column presents the MOF probability ratios with Hb between the 10th and 90th percentile of Hb to median Hb. When Hb is included in a model it contributes as a spline function. All Hb values are g/dL.

Abbreviations: BMI, body mass index; Hb, hemoglobin; MOF, major osteoporotic fracture.
