Abstract

Objective: This study aimed to identify factors at hospital discharge that predict physical activity and walking outcomes in the first 6 months after stroke.

Data sources: Searches were conducted in CINAHL (EBSCO), Web of Science, PubMed and Scopus from inception to 30 April 2024. Reference lists of included articles were manually screened to identify additional studies.

Review methods: Studies of adults with stroke reporting predictors at hospital discharge and outcomes of physical activity or walking across the first 6 months after hospital discharge were included. Two reviewers independently screened titles, abstracts and reviewed full texts. Quality of included studies was assessed with Quality in Prognostic Studies screening tool. A narrative synthesis was undertaken.

Results: The search strategy retrieved 7834 studies, from which 6 eligible studies were identified, including a total of 1433 participants. Overall, studies had a low risk of bias. Age, balance, walking speed and walking distance at hospital discharge predicted physical activity outcomes after stroke ($n=2$ studies). Cognition, lower limb cycling rhythm and self-efficacy for walking at hospital discharge predicted walking outcomes after stroke ($n=4$ studies).

Conclusions: A range of factors predicted physical activity and walking outcomes 6 months after stroke. Physical capabilities at discharge appear to be a predictor of these outcomes; however, this needs to be interpreted with caution. Diverse measures and time points were used across studies to characterise physical activity and walking outcomes, highlighting the need for consistency in measurement and longitudinal studies in stroke research.

Stroke is one of the leading causes of disability worldwide and the second most common cause of global disability-adjusted life years (DALYs).¹ Most individuals with stroke remain physically inactive and spend most of their day in sedentary behaviours.^{2,3} This increases their risk of recurrent stroke^{4,5} and poor health outcomes.⁶ Further, walking recovery, a common approach to increasing physical activity, is suboptimal post-stroke.⁷ Most individuals with stroke continue to report limited walking and poor satisfaction with walking outcomes.⁷ Thus, targeted interventions aimed at improving and maintaining physical activity and walking after stroke are necessary to reduce burden and improve long-term health outcomes.^{8,9} Understanding factors amenable to intervention is essential for designing successful interventions.

Hospital discharge is a critical juncture in rehabilitation after stroke. Understanding factors at hospital discharge predictive of physical activity and walking in the months following is crucial for several reasons. First, predictors identified around hospital discharge could drive decisions regarding both the service and content of rehabilitation post-discharge. Second, as physical activity and walking ability are integral for transitioning to home and community, understanding important factors at discharge could influence decisions regarding discharge destination. Lastly, if likely predictors of activity and walking ability are known at discharge, future inpatient intervention approaches could focus on optimising these factors. The subacute phase is a key time period where neurological recovery potential is high.^{10,11} Targeted interventions in a supportive rehabilitation environment could further minimise physical inactivity behaviour that often occurs in later stages when individuals with stroke transition home after discharge.

To date, a 2018 systematic review¹² found that after stroke, factors including cardiorespiratory fitness, fatigue, falls and balance self-efficacy were significantly associated with physical activity. However, the majority of studies were cross sectional and included participants in the chronic phase of stroke.¹² Another systematic review¹³ investigated predictors of independent walking across the subacute phase of stroke and found a

variety of factors including age, an intact corticospinal tract, cognition, sitting balance and continence early post-stroke onset.¹³ This review, however, included only independent walking as an outcome and restricted inclusion to non-ambulatory individuals with stroke.¹³ Thus, it is not clear what factors at hospital discharge prospectively predict physical activity levels, or walking independence, speed or distance after stroke, as they transition home and recover. This systematic review aims to determine the following: (1) What factors at hospital discharge predict physical activity outcomes within first 6 months after stroke? and (2) What factors at hospital discharge predict walking outcomes within first 6 months after stroke?

Methods

This systematic review followed the Preferred Reporting Items for Systematic Reviews and Meta-analysis (PRISMA) guidelines¹⁴ and was prospectively registered with the International Prospective Register of Systematic Reviews (CRD42020202323).

Inclusion and exclusion criteria were determined a priori. Studies of human participants with first or recurrent stroke, aged 18 years or above, were included. Primary research studies consisting of prospective cohort studies, randomised trials and prognostic and predictive studies, reporting on outcomes of physical activity or walking across the first 6 months after stroke and exploring independent factors around the time of hospital discharge were included. Studies that provided univariate or multivariate statistics of prediction between the independent factors and physical activity or walking outcomes were included. Studies reporting outcomes of physical activity, such as accelerometer-derived number of steps, frequency, intensity, duration of physical activity¹⁵ and physical activity diaries or questionnaires, or walking recovery outcomes such as walking independence, speed and distance⁷ were included. Studies not in English were excluded.

Electronic search strategies were developed in consultation with a research librarian and included

keywords relevant to physical activity and walking after stroke (Supplemental material S1). Search strategies were used across the bibliographic databases of CINAHL (EBSCO), Web of Science, PubMed and Scopus from inception to 30 April 2024. Where relevant, Medical Subject Headings and indexed terms were used to provide specific subject headings for each database. The search was limited to the English language and to human studies. The reproducible searches for all databases are available in the Supplemental material. Citation searches of included studies were undertaken in Web of Science. Reference lists of included studies were screened to identify any further relevant studies. For each database, auto alerts were set up to provide monthly updates of new literature until 30 April 2024.

The yield from database searches was uploaded to the web-based collaboration software platform, Covidence (Available at www.covidence.org). Duplicates were removed by using EndNote's duplicate identification strategy. All titles and abstracts were screened against the eligibility criteria independently by two reviewers (two of NN, NM, SB and SK). In cases where it was not clear if eligibility criteria had been met or reviewers did not agree, papers were retained for full-text review. Full-text copies were reviewed independently by two reviewers (NN and SK). Any disagreement was resolved with a third reviewer (NM and SB).

The quality of included studies was assessed with the Quality in Prognostic Studies (QUIPS) screening tool for prognostic factor studies.¹⁶ The screening tool consists of six domains of bias for prognostic factors: study participation, study attrition, prognostic factor measurement, confounding measurement, outcome measurement and analysis and reporting. Studies were rated as having low, moderate or high risk of bias in relation to each of these domains.¹⁶ Included studies were assessed for quality independently by two reviewers (NN and NM) with disagreements resolved by a third reviewer (SK).

Data were extracted by one investigator (NN), stored in Covidence and independently cross-checked by another reviewer (SK and NM). Data

were cross-checked for author, study and journal details, including date, title and details of publication, and participant data related to age and sex, total number of participants in the study and time after stroke. Information related to physical activity and walking outcomes (e.g., measurement and time point), and statistical association details were extracted and checked.

Descriptive data synthesis was undertaken based on participant characteristics and identified factors at discharge related to physical activity and walking outcomes after stroke and the association/correlational statistics. A meta-analysis of the pooled estimates between identified factors and outcomes of physical activity and walking recovery was planned but was not possible due to heterogeneity across studies for reported predictors and physical activity and walking recovery outcomes. Thus, a narrative synthesis was conducted.

Results

A total of 7830 citations were retrieved from the 4 databases and 4 identified from reference list searches, thus yielding a total of 7834 studies. After removing duplicates, 6144 studies were screened for titles and abstracts. Of these, 234 studies were retrieved as full text. Following full-text review, six studies^{17–22} were included in final synthesis (Figure 1) and are summarised in Table 1.

Studies were published between 2005 and 2020 and included a total of 1433 participants (study samples ranging from $n=36$ to 1023). Four studies reported outcome measures related to walking and two studies reported outcomes related to physical activity. All studies were longitudinal observational cohort studies, presenting multivariate statistics of association.

All studies had an overall low risk of bias (Table 2). All studies had a low risk of selection bias. Four (67%) studies had a low^{17–19,22} and two (33%) had a moderate^{20,21} risk of attrition bias. All studies had a low risk of measurement bias in relation to the prognostic/predictive factors and measurement bias in relation to the outcome. Four (67%) studies had a moderate risk of bias

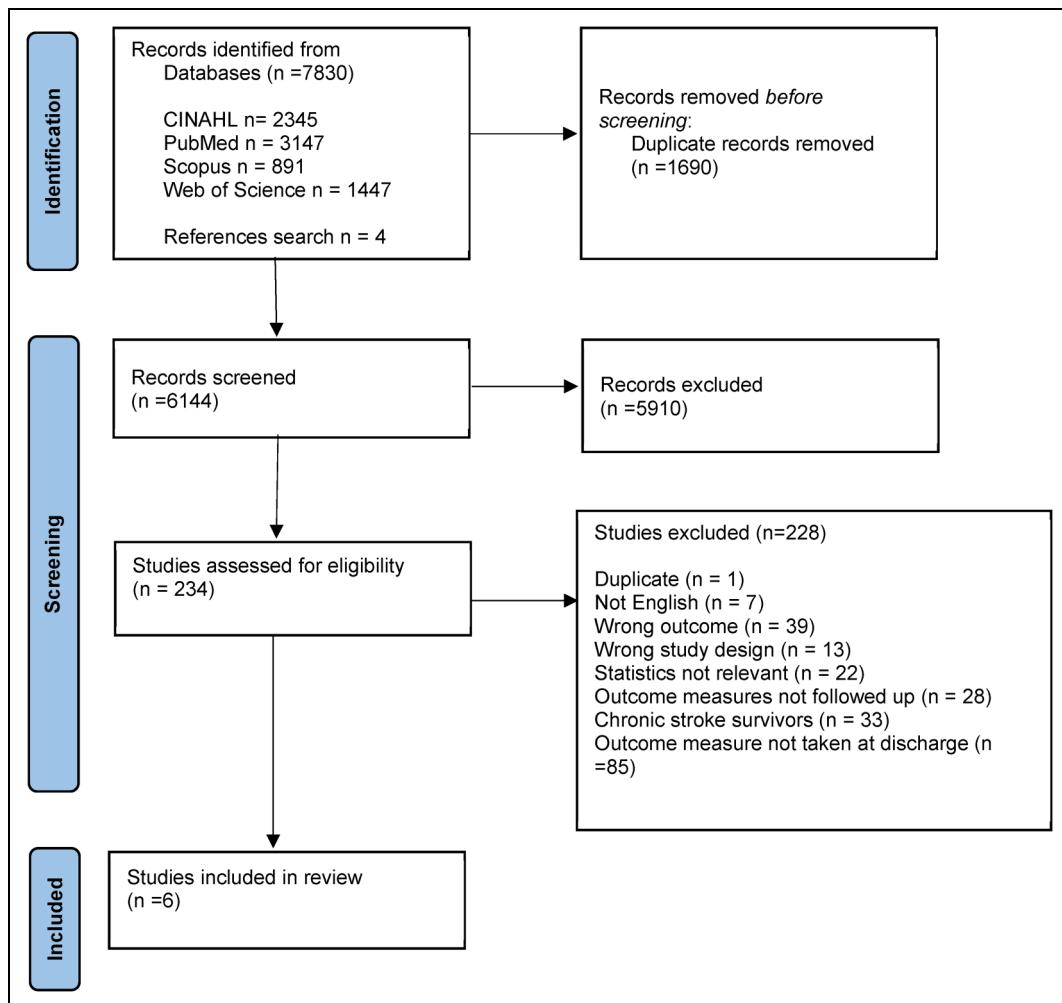

Figure 1. PRISMA flow chart of systematic review search process.

due to confounding,^{19–22} and two (33%) had a high risk.^{17,18}

Two studies ($n=91$) investigated factors at hospital discharge able to predict physical activity outcomes at 1,¹⁹ 3^{19,22} and 6 months¹⁹ after discharge (Table 1). Both studies reported daily step counts, measured with different accelerometers, the ActivPAL™¹⁹ and a custom ankle-mounted accelerometer.²² In addition, accelerometer-derived time in high intensity (intensity) and long duration (frequency) walking bouts¹⁹ and self-reported intensity and participation in physical activity²² was reported.

Walking distance (6-minute walk test (6MWT)) at hospital discharge predicted daily step count, intensity and frequency of physical at 1 month after discharge.¹⁹ Comfortable walking speed,²² step test performance,²² ankle dorsiflexor strength²² and walking distance and pre-stroke physical activity¹⁹ predicted physical activity 3 months after hospital discharge. Age, walking distance, pre-stroke physical activity¹⁹ and executive function¹⁹ at hospital discharge predicted physical activity 6 months later.

Four studies ($n=1342$) investigated factors at discharge associated with walking outcomes at

2,²⁰ 3¹⁸ and 6 months^{17,21} after discharge (Table 1). Each study reported a different measure of walking, including clinical outcomes of walking independence,²¹ walking speed and walking distance,¹⁸ self-reported outcomes of walking participation,²¹ life-space assessment²⁰ and perceived walking limitation and recovery.¹⁷

Walking independence at 6 months after discharge was predicted by cognitive function, when adjusted for age, lower limb strength and side of stroke ($R^2=0.424$ to 0.454).²¹ Walking speed at 3 months after hospital discharge was predicted by the ability to cycle at a constant rate with and without resistance at discharge ($R^2=0.40$),¹⁸ while walking distance and the ability to climb stairs at 3 months after hospital discharge were predicted by the ability to cycle at a constant rate with resistance only ($R^2=0.21$ and 0.26 , respectively).¹⁸

Self-reported walking participation at 2 months after discharge²⁰ was predicted by female sex, age, falls self-efficacy, cognitive function, walking speed (via Timed Up and Go test) and length of hospital stay collected at hospital discharge ($R^2=0.54$). Walking participation at 6 months²¹ was predicted by cognitive function when adjusted for age, lower limb strength and side of stroke ($R^2=0.497$ to 0.613).²¹ Self-reported perceived walking limitation and recovery at 6 months were predicted by perceived behavioural control only (adjusted $R^2=0.19$ and 0.11 , respectively).¹⁷

Discussion

This systematic review identified 6 studies ($n=1433$, low risk of bias) that investigated factors at hospital discharge predicting physical activity (2 studies) and walking outcomes (4 studies) during the first 6 months after stroke. Physical capabilities at discharge appear to be a predictor of these outcomes; however, this needs to be interpreted with caution. Diverse measures and time points were used across studies to characterise physical activity and walking outcomes across the subacute phase of stroke, preventing meta-analysis. Physical activity and walking outcomes identified in this review represent distinct clinical targets in post-stroke rehabilitation. Walking independence,^{28,29} speed^{23,30,31} and distance^{23,29,30} capture different targets of recovery³² and relate to varied participation goals for people living with stroke.^{24,33} Consequently, the diverse predictors found in this review are unsurprising. Nevertheless, this review highlights the need for consistency in outcome measurement and for longitudinal studies in stroke research.

This review found that most studies that measured physical or walking capability at hospital discharge determined that it significantly predicted physical activity or walking outcomes up to 6 months later but only explained a part of the outcome. While it is likely that higher physical capability will enable improvements in physical

activity and walking, other factors will need consideration and intervention when aiming to increase long-term physical activity and walking outcomes after stroke.²⁵ This is supported by the finding that various measures of cognitive function often contributed to the prediction equations in the examined studies in this review. This finding supports previous studies that have identified that factors important in behaviour change contribute to recovery of physical activity and walking post-stroke.^{26,27,34,35} This supports the premise that to successfully enhance long-term physical activity and walking recovery, rehabilitation should include strategies such as behaviour change techniques.^{9,36,37} Clearly, further investigation is required to understand what techniques to select, for whom, when and how to optimally use these techniques to enhance recovery of physical activity and walking as individuals with stroke transition home.

Previous research has identified factors on hospital admission such as age^{38–41} and stroke severity^{39,42,43} that predict physical activity 6 months after stroke. In contrast, this systematic review included papers that identified modifiable predictors at a later time point which could be targeted with tailored intervention during rehabilitation. Understanding what modifiable factors predict positive physical activity and walking outcomes can help clinicians focus on factors to optimise prior to discharge, set realistic goals and foresee needs for additional care after discharge. In addition, it is of clinical importance to identify individuals with stroke at risk of becoming inactive as they transition home. This is a key step required to enable tailored and proactive strategies to improve long-term physical activity and walking outcomes after stroke.

Diverse outcomes of physical activity and walking identified in this review call for a need for consistency in measures used in post-stroke rehabilitation and research. A recent international consensus on measuring physical activity recommends using device-based measures for step count.¹⁵ Likewise, the Stroke Recovery and Rehabilitation Roundtable (SRRR)⁴⁴ recommends the use of standardised measurement for walking

outcomes, including tests such as 10-metre walk test for walking speed. Implementing a standardised protocol for collecting data, such as wear time of devices, walkway length for tests and frequency of data collection, may be useful to ensure consistency across different studies. Consistent measurement protocols would enable pooling data from multiple studies, facilitating meta-analyses.

There was also a lack of consistency in the time points used for follow-up by studies included in this review, ranging from 4 weeks to 6 months after stroke, making it difficult to draw conclusions. Measurements of physical activity and walking outcomes at fixed time points,⁴⁵ across the subacute stage after stroke,⁴⁶ are recommended. Consensus from SRRR⁴⁵ recommends that measurement of outcomes should commence within first 7 days of stroke and occur at designated intervals up to at least 3 months post-stroke. Standardising fixed time points could enable longitudinal analyses of data, thereby facilitating identification of predictors of recovery after stroke and intervention effectiveness.

Limitations of this review must be acknowledged. The review found only 6 studies that met inclusion criteria, with participant numbers ranging from $n = 36$ to 1023, which highlights the need for prospective longitudinal studies to explore factors associated with physical activity and walking after stroke. Positively, the studies had low risk of bias and used multivariate statistics. However, there was heterogeneity of outcome measures and time points in the included studies, which limited synthesis via a meta-analysis, highlighting the need for consistency in measurement in future research.

This review found a range of factors related to physical activity and walking outcomes across the first 6 months following hospital discharge, with physical capability as the most frequently identified predictive factor. More larger longitudinal studies with a breadth of predictor variables and standardised outcome measures at agreed time points are needed to inform the design of targeted interventions to improve physical activity and walking recovery after stroke.

Clinical messages

- Physical capability at hospital discharge contributes to prediction of physical activity or walking outcomes across the first 6 months of returning home after stroke.
- Different factors at hospital discharge predict the diverse measures used to characterise physical activity and walking outcomes across the subacute phase post-stroke.
- Consistency in measurement of physical activity and walking after stroke is needed.
