Abstract

Metformin is the mainstay therapy for type 2 diabetes (T2D) and many patients also take salicylate-based drugs [i.e., aspirin (ASA)] for cardioprotection. Metformin and salicylate both increase AMP-activated protein kinase (AMPK) activity but by distinct mechanisms, with metformin altering cellular adenylate charge (increasing AMP) and salicylate interacting directly at the AMPK β 1 drug-binding site. AMPK activation by both drugs results in phosphorylation of ACC (acetyl-CoA carboxylase; P-ACC) and inhibition of acetyl-CoA carboxylase (ACC), the rate limiting enzyme controlling fatty acid synthesis (lipogenesis). We find doses of metformin and salicylate used clinically synergistically activate AMPK *in vitro* and *in vivo*, resulting in reduced liver lipogenesis, lower liver lipid levels and improved insulin sensitivity in mice. Synergism occurs in cell-free assays and is specific for the AMPK β 1 subunit. These effects are also observed in primary human hepatocytes and patients with dysglycaemia exhibit additional improvements in a marker of insulin resistance (proinsulin) when treated with ASA and metformin compared with either drug alone. These data indicate that metformin–salicylate combination therapy may be efficacious for the treatment of non-alcoholic fatty liver disease (NAFLD) and T2D.

AUTHOR CONTRIBUTIONS

Rebecca Ford, Morgan Fullerton, Stephen Pinkosky and Gregory Steinberg designed the study. Rebecca Ford, Emily Day, Morgan Fullerton, Stephen Pinkosky, Adam Bujak., Brennan Smith, Katarina Marcinko, Regje Blümer and Justin Crane performed experiments and data analyses. Hertz C. Gerstein analysed human subject data and provided consultation. John Scott, Jonathan Oakhill and Bruce Kemp contributed the AMPK *in vitro* studies, Rebecca Ford, Stephen Pinkosky, Hertz C. Gerstein, Bruce Kemp and Gregory Steinberg wrote the manuscript. All authors contributed to editing the final manuscript draft.

INTRODUCTION

Non-alcoholic fatty liver disease (NAFLD) is estimated to affect nearly 40 % of all adults and more than 80 % of those with type 2 diabetes (T2D) [1]. Elevated rates of liver fatty acid synthesis (*de novo* lipogenesis) cause NAFLD in humans [2] and NAFLD may promote the development of T2D by reducing liver insulin sensitivity [3]. Therefore pharmacological strategies aimed at inhibiting liver lipogenesis may be effective to reduce or reverse the prevalence of NAFLD and improve insulin sensitivity.

AMP-activated protein kinase (AMPK) is an $\alpha\beta\gamma$ heterotrimer that inhibits a rate limiting step of liver fatty acid synthesis through inhibitory phosphorylation of acetyl-CoA carboxylase 1 and 2 [ACC1 and ACC2; P-ACC]; 4,5]. Importantly, mice deficient in the AMPK phosphorylation sites on ACC accumulate enhanced levels of liver fat and develop insulin resistance [6], indicating the importance of this pathway in maintaining metabolic homeostasis. Metformin and salicylate [the active metabolite of aspirin (ASA) and salsalate] both activate AMPK, albeit by different mechanisms: metformin increases AMPK activity indirectly by inhibiting mitochondrial respiration and increasing AMP levels [7], whereas salicylate-induced activation requires the AMPK β 1 subunit [8]. Metformin- and salicylate-based therapeutics (ASA and salsalate) improve liver insulin sensitivity [9–11], effects which may involve the activation of AMPK and subsequent P-ACC [6,8].

Given that metformin and salicylate activate AMPK via distinct mechanisms, we hypothesized that co-treatment using these drugs would synergistically increase liver AMPK activity/P-ACC, reduce lipogenesis and improve insulin sensitivity. In the present study, we provide novel evidence that low, clinically-relevant doses of metformin and salicylate synergistically activate AMPK to inhibit lipogenesis in primary hepatocytes from mice and humans. Synergistic activation of AMPK occurs in cell-free assays and is dependent on the expression of the AMPK β 1 isoform. Importantly, combination therapy also improves glucose tolerance, hepatic insulin sensitivity and reduces the accumulation of liver fat in high fat diet (HFD)-fed mice whereas lowering pro-insulin levels (a marker of insulin secretion/sensitivity [12]) in over 8000 human subjects with dysglycaemia over the effects of either drug alone.

MATERIALS AND METHODS

Experimental design

Male C57bl/6 mice were maintained on a 12-h light dark cycle (lights on at 7.00 am) and housed in a pathogen-free facility at 23 °C with bedding enrichment. At 8 weeks of age, mice were either killed to obtain primary hepatocytes or switched from a standard chow diet to a HFD [60 % kcal (1 cal \equiv 4.184 J) from fat, diet D12492 from Research Diets] for 5 weeks. At 13 weeks of age, glucose tolerance tests (GTTs; described in detail below) were performed to confirm a metabolically compromised phenotype (result not shown) and animals were assigned to four groups matched for weight and glucose tolerance. Since we were specifically interested in testing the effects of the low-dose metformin and/or salsalate in obesity, we did not study control chow-fed mice. Importantly, the HFD-fed mice used in the current study had comparable levels of obesity/adiposity, glucose tolerance, insulin

resistance and liver triglycerides (TG) compared with those of our recent studies in which both chow and HFD-mice were studied [6,13]. As dictated by design, mice that were not obese (<32 g) after the initial 5 weeks of HFD were excluded from the study and all further analyses. The four groups were then randomly assigned to begin feeding of HFD containing no drug [control], 2.5 g/kg metformin, 1 g/kg salsalate or both 2.5 g/kg metformin and 1 g/kg salsalate (metformin + salsalate) for an additional 5 weeks.

Study approval

All animal procedures were approved by the McMaster University Animal Ethics Research Board (AUP #: 12–12-44). Human results were obtained from data collected during the Outcome Reduction with an Initial Glargine Intervention (ORIGIN) trial (NCT00069784, [14]), which was approved *a priori* by the ethics committee at each site. Written informed consent was obtained from all participants prior to inclusion in the study.

Primary cell culture

Mouse primary hepatocytes were obtained from C57bl/6 mice by collagenase digestion, as previously described [6,15]. For human primary hepatocyte experiments, cryopreserved primary human hepatocytes (Triangle Research Labs) were thawed, centrifuged and re-suspended in complete William's E medium (11 mM glucose) containing 10 % FBS and plated in 24-well collagen coated plates at 0.35×10^6 cells/well and allowed to adhere for 4 h. Donors of cryopreserved human hepatocytes were male [age 46, body mass index (BMI) 23.5] and female (age 59, BMI 29), were non-drug users (including alcohol), non-smokers. All experiments were performed the following morning after hepatocytes were serum starved for 3- (mouse) or 18- (human) h in the William's E medium (11 mM glucose). For [^3H]-acetate fatty acid synthesis, cells were treated with no drug, metformin, salicylate or metformin + salicylate, [^3H]-acetate (5 $\mu\text{Ci}/\mu\text{l}$) and sodium acetate (0.5 mM) for 4 h in serum-free William's E medium (11 mM glucose) as described [6]. Medium was then removed and cells were washed twice with PBS before extraction of total lipids using chloroform–methanol [16]. Drug synergy in fatty acid synthesis experiments was calculated using the Chou–Talalay method and CompuSyn software [17,18]. [^{14}C]-palmitate fatty acid oxidation was performed as described previously [6], with minor modifications including pre-treatment of hepatocytes for 1 h with drugs followed by 4 h treatment with 200 μM palmitate (complexed with 2 % BSA, with radiolabel at 0.5 $\mu\text{Ci}/\text{ml}$), 500 μM L-carnitine and drugs in serum-free media before the cells and media were collected for the assay. For Western blots, cells were treated with vehicle or drugs for 2 h. Medium was then removed and cell lysis buffer applied to cells rapidly on ice and plates snap frozen on liquid nitrogen, as described previously [19]. Lysates were stored at -80°C for further analyses.

AMPK activity assay

Heterotrimeric human AMPK GST- $\alpha 1\beta 1\gamma 1$ was expressed by transient transfection of COS7 cells cultured in Dulbecco's Modified Eagle's Medium supplemented with 10 % FBS as described previously [20]. Transfected cells were harvested by washing with ice-cold PBS followed by rapid lysis *in situ* using 1 ml of lysis buffer [50 mM Tris/HCl, pH 7.4, 150 mM NaCl, 50 mM NaF, 1 mM NaPPI, 1 mM EDTA, 1 mM EGTA, 1 mM DTT, 1 % (v/v) Triton X-100]. Cellular debris was removed by centrifugation, after which AMPK was isolated

from the lysates on glutathione Sepharose 4B (GE Life Sciences), extensively washed with lysis buffer and then dephosphorylated with λ -phosphatase (2 mM MnCl₂, 2 h, 22 °C) prior to elution in storage buffer 50 mM Tris/HCl (pH 7.4), 150 mM NaCl, 10 % glycerol, 2 mM TCEP [tris(2-carboxyethyl)phosphine], 20 mM reduced glutathione. For AMPK $\alpha 1\beta 1 \gamma 1$ and $\alpha 1\beta 2 \gamma 1$ expressed in bacteria, all procedures were as described previously [20].

AMPK activity was determined by phosphorylation of the SAMS peptide (HMRSAMSGHLHLVKRR) using 100 μ M SAMS, 200 μ M [γ -³²P] ATP, 5 mM MgCl₂ and indicated ligands in 25 μ l of reaction volume at 30 °C. Reactions were terminated after 10 min by spotting 15 μ l on to P81 phosphocellulose paper (Whatman) and washing in 1 % phosphoric acid [21]. Radioactivity was quantified by scintillation counting.

Metabolic studies

GTTs and insulin tolerance tests (ITTs) were performed by intraperitoneal injection of glucose (0.8 g/kg body weight) or human insulin (1 unit insulin/kg body weight) respectively and blood glucose measured by Aviva blood glucose monitor (Roche) from a small tail vein nick at the time points indicated. Mice were fasted for 6 h prior to all tolerance tests. Respiratory exchange ratio (RER) was assessed using a Columbus Laboratory Animal Monitoring System [22]. Whole body adiposity was measured using computed tomography [22]. Fasting (12 h) and fed blood samples were collected by tail vein bleed for serum measurements. Commercially available ELISA kits were used to measure serum salicylate (Neogen) and insulin [Millipore (rodent) and Mercodia (human)]. Serum metformin levels were measured by MS using a PE/Sciex 3000 LC–MS/MS system after solvent extraction. Phenformin was used as an internal standard and metformin was eluted at 3.5 min on the chromatograph.

Hyperinsulinaemic–euglycaemic clamps

Hyperinsulinaemic–euglycaemic clamps were performed as previously described [6]. Briefly, 5 days after cannulating the right jugular vein, mice were fasted for 6 h then infused with D-[3-³H]-glucose for 1 h for assessment of basal glucose disposal. A human insulin infusate containing D-[3-³H]-glucose was then applied and blood glucose monitored and titrated with 50 % dextrose infused at a variable rate to achieve and maintain euglycaemia. Basal and clamped glucose disposal rates (GDRs) and hepatic glucose production (HGP) rates were calculated as previously stated [6]. All tissues were rapidly dissected, snap frozen in liquid nitrogen and stored at – 80 °C for later analyses.

Immunoblotting, histological and biochemical analyses

Tissue or cell lysates were diluted with Western sample buffer and loaded in SDS/PAGE (7.5 % gels) as previously described [6]. After resolution of proteins by molecular mass, proteins were transferred to polyvinylidene difluoride membranes and blocked in 5 % BSA. All primary antibodies were obtained from Cell Signaling Technologies [P-ACC Ser^{79/212}, ACC, β -actin, P-Akt/PKB (protein kinase B) Ser⁴⁷³, P-Akt/PKB Thr³⁰⁸, Akt/PKB] and used at concentrations of 1:1000 except β -actin which was used at 1:5000. For liver histology, all tissues were fixed in formalin (for at least 48 h), paraffin embedded and sectioned for

haematoxylin and eosin (H & E) staining. After staining, two sections from each sample were imaged in triplicate. Liver lipid levels were measured by glycerol assay (Sigma) [6].

Analyses and modelling of clinical population data

Linear regression analyses were performed on proinsulin levels from patients recruited into the ORIGIN trial [14]. All participants had some degree of glucose elevation that ranged from slightly elevated glucose to clinically important degrees of hyperglycaemia [i.e. median fasting plasma glucose (FPG) = 6.9 mmol/l and median glycated haemoglobin A1c (HbA1c) = 6.4%]. Associations of metformin and/or ASA with proinsulin levels were obtained after adjusting for age, sex, weight, FPG levels, HbA1c and insulin levels.

Statistical analyses

All values are reported as mean \pm S.E.M. Data were analysed –using Student's *t* tests or one-way ANOVA or repeated measures ANOVA with Tukey's or Bonferroni post-hoc tests where appropriate. Differences were considered significant when $P < 0.05$.

RESULTS

Metformin and salicylate synergistically activate AMPK and inhibit lipogenesis in mouse primary hepatocytes

High doses of both metformin (0.5 mM) [6] and salicylate (3–5 mM) [8] regulate fatty acid metabolism in primary mouse hepatocytes through AMPK-mediated P-ACC. P-ACC is considered the best measure of AMPK activation in cells and tissues as it accounts for both allosteric and covalent modification components of AMPK activation [23]. In the present study, we show that metformin (Figure 1A) and salicylate (Figure 1B) both dose-dependently inhibit *de novo* fatty acid synthesis in mouse primary hepatocytes when administered alone (IC₅₀ values of 425 μ M and 6.1 mM respectively). When 0.1 mM metformin (a concentration observed in the portal vein [24]) was combined with 0.5 mM salicylate (a serum concentration achieved following ASA administration [25]), P-ACC was increased ~2-fold despite undetectable changes with individual doses (Figure 1C). Low doses of metformin (0.1 mM) also enhanced P-ACC when combined with salicylate at 1 or 3 mM (Figure 1C) and this effect was conserved when using higher concentrations of metformin (0.25 mM; Supplementary Figure S1A). As expected [6], the inhibitory effects on hepatocyte lipogenesis inversely mirrored the enhanced P-ACC at these combination doses (Figure 1D; Supplementary Figure S1B). The Chou–Talalay mathematical model theorem for drug synergy revealed a synergistic relationship between the two drugs, as indicated by combination Index (CI) values < 1 (Figure 1E; Supplementary Figure S1C).

Fatty acid oxidation was unaltered in the presence of low doses of metformin (0.1 mM) or salicylate (0.5 mM) alone or in combination (Figure 1F) and although higher dose salicylate (3 mM) increased fat oxidation, no further increase was observed with high dose metformin (0.5 mM; Supplementary Figure S1D). This is not unexpected since metformin inhibits complex-1 of the respiratory chain [26,27] which is required for the oxidation of fatty acyl-CoA and is consistent with findings from previous studies in hepatocytes [6,28] and skeletal muscle [29].

In cell-free assays, AMP (generated in hepatocytes by metformin [7]) and salicylate increased the activity of purified, non-phosphorylated AMPK $\alpha 1\beta 1\gamma 1$ heterotrimers by greater than 60-fold, but only had minor effects on allosteric activation when administered alone (Figure 1G; Supplementary Figure S1E). Synergy was eliminated in assays using a $\alpha 1\beta 2\gamma 1$ complex, confirming the necessity of the β -subunit isoform for the interaction (Supplementary Figure S1F). These data are the first to indicate that metformin and salicylate synergistically increase AMPK activity/P-ACC through allosteric mechanisms involving AMPK $\beta 1$ independently of upstream kinases.

Metformin and salicylate synergistically activate AMPK and inhibit lipogenesis in human primary hepatocytes

Since AMPK subunit expression profiles differ between mouse and human liver [26], we examined the responses to metformin and salicylate in primary human hepatocytes to assess the translational potential of our findings. Metformin and salicylate each generated dose-dependent inhibition of fatty acid synthesis (IC_{50} values of 616 and 522 μM respectively; Figure 2A). Importantly, equimolar doses of metformin and salicylate in human hepatocytes further reduced the IC_{50} for fatty acid synthesis to 296 μM (Figure 2A). As observed in mouse primary hepatocytes, metformin and salicylate also generated parallel synergistic increases in AMPK activation/P-ACC (Figure 2B) and suppression of lipogenesis (Figure 2C).

Liver lipids are synergistically reduced in high fat diet-fed mice treated with low-dose metformin and salsalate

To evaluate whether synergistic effects are also observed *in vivo*, mice were fed a diet containing 60 % kcal from fat (HFD) for 5 weeks followed by 5 weeks of HFD containing no drug, 2.5 g/kg metformin, 1 g/kg salsalate or 2.5 g/kg metformin plus 1 g/kg salsalate. These doses of metformin and salsalate were chosen based on pilot experiments that generated low systemic venous blood levels of metformin (~8–40 μM ; Supplementary Figure S2A) and salicylate (~150–300 μM ; Supplementary Figure S2B) and closely mimic those achieved by dosing in humans [i.e. comparable to ~0.5–1.5 g/day metformin [9,30,31], ASA (~1 g/day) or salsalate (~0.75 g/day); 25,32,33]. Consistent with our findings in cultured hepatocytes, liver P-ACC was enhanced in mice receiving metformin–salsalate therapy (Figure 3A). Chronic treatment did not affect weight gain (Figure 3B) or adiposity (Figure 3C), a finding consistent with data from metabolic cages indicating that food intake (Supplementary Figure S2C) and energy expenditure (Supplementary Figure S2D) were unaltered. Despite comparable degrees of adiposity, metformin + salsalate treated mice displayed lower RER values (Figure 3D) (which can indicate reduced rates of whole-body *de novo* fatty acid synthesis [34]) and a strong tendency for reduced liver lipid (H & E staining; Figure 3E and liver glycerol; Figure 3F).

Insulin sensitivity is enhanced in high fat diet-fed mice treated with metformin and salsalate

Metformin + salsalate treatment improved glucose (Figure 4A) and insulin tolerance (Figure 4B) and lowered fasting glucose (Figure 4C) compared with control, metformin or salsalate only. Serum insulin also tended to be lowest in mice receiving metformin + salsalate diet

(Figure 4D). In hyperinsulinaemic–euglycaemic clamp experiments, all treatments tended to increase glucose infusion rates (GIRs; Supplementary Figures S2E and S2F), however metformin–salicylate combination therapy had the largest effect on liver insulin sensitivity as indicated by reductions in HGP (Figure 4E) and greater suppression of hepatic glucose output (Figure 4F) compared with the effects of metformin and salicylate alone. Serum glucose (Supplementary Figure S2G) and steady-state serum insulin levels (Supplementary Figure S2H) were comparable between groups during the clamp, confirming clamped states and insulin equality respectively. There were no effects of treatments on GDR (Supplementary Figure S2I) or non-esterified fatty acids (NEFA; Supplementary Figure S2J), indicating that peripheral insulin sensitivity (skeletal muscle and adipose tissue) was unaltered. Insulin signalling, as assessed by P-Ser⁴⁷³-Akt–Akt and P-Thr³⁰⁸-Akt–Akt was unaltered in clamped livers of mice from any treatment group (Supplementary Figure S2K).

Metformin and ASA independently reduce proinsulin in humans with dysglycaemia

Human hepatocytes were sensitive to salicylate at concentrations achievable following the intake of ASA (Figure 2A) [25]. Therefore we used data collected as part of the previously completed ORIGIN trial [33] to explore the metabolic effect of metformin and ASA in 8281 people with either prediabetes or diabetes (median FPG = 6.9 mmol/l and median HbA1c = 6.4 %) in whom proinsulin and insulin levels were measured. In large clinical studies (such as ORIGIN), fasting pro-insulin levels are considered a reliable indicator of insulin resistance in individuals with T2D [12]. After adjusting for covariants, metformin ($P < 0.0001$) and ASA ($P = 0.025$) were both independently associated with a lower proinsulin level (Table 1) with combination therapy resulting in further reductions (-0.1801 ± 0.0331 , $P < 0.0001$, $n = 3381$; Table 1).

DISCUSSION

Elevated levels of *de novo* fatty acid synthesis contribute to the aetiology of NAFLD and insulin resistance [2,6] and are observed in insulin resistant [35], diabetic [36] and obese [37] humans under fasting and fed conditions. In addition, recent evidence directly confirms the contribution of *de novo* lipogenesis to fatty liver disease in humans using NMR spectroscopy [2], highlighting the importance of targeting this process for therapeutic intervention in NAFLD. In agreement with previous reports [6,38–40], we show that metformin and salicylate dose-dependently inhibit *de novo* lipogenesis in primary hepatocytes from rodents (Figures 1A and 1B). Whereas the concentration of metformin that elicited a 50 % reduction in lipogenesis was comparable between mice and human hepatocytes (Figures 1A and 2A), the IC₅₀ for salicylate was an order of magnitude lower in the human cells (Figure 2A) and comparable to serum levels achieved following ingestion of a regular strength ASA [25], revealing notably greater sensitivity of human primary hepatocytes to salicylate. We also demonstrate that priming of mouse and human hepatocytes with clinical concentrations of metformin that have no effect on fatty acid synthesis on their own, dramatically reduce salicylate-induced inhibition of fatty acid synthesis and activate AMPK in primary hepatocytes and *in vitro* assays. These data provide the first evidence that metformin and salicylate synergistically activate AMPK and reduce *de novo* fatty acid synthesis in mouse and human primary hepatocytes at clinically achievable

doses. This suggests that low serum levels of salicylate (i.e. closer to those achieved with extra strength ASA [25]) may be appropriate for inhibiting fatty acid synthesis, particularly in NAFLD where hepatic fatty acid synthesis is enhanced. Future studies are required to determine why human hepatocytes have enhanced sensitivity to salicylate-induced inhibition of lipogenesis compared with those of mice.

Consistent with the synergistic effects of metformin and salicylate on liver AMPK activation and *de novo* lipogenesis, we found that low doses of metformin and salicylate activate AMPK/enhance P-ACC (Figure 3A) and tended to lower TG/NAFLD (Figures 3E and 3F) in livers of mice made obese through feeding of a HFD over the effect of either drug alone. Furthermore, hyperinsulinaemic–euglycaemic clamp experiments revealed that the most profound improvement in insulin sensitivity with combination treatment occurred in the liver, as indicated by synergistic inhibition of HGP (Figure 4F) and elevated percentage suppression of hepatic glucose output (Figure 4G) in metformin + salicylate treated animals over those treated with either drug alone, effects that were also observed in the absence of any notable differences in peripheral GDRs (Figure S2I). These findings are consistent with previous reports indicating that the liver is the primary target of metformin and salicylate [41,42].

We examined the effects of metformin + salicylate treatment in HFD-fed mice since they are considered a clinically relevant model of human obesity and insulin resistance; however, it is known that feeding of a HFD suppresses liver *de novo* lipogenesis. Therefore, given that metformin–salicylate therapy suppressed *de novo* lipogenesis and had no effect on fatty acid oxidation, this lower starting lipogenic rate may have explained why metformin–salicylate combination therapy only had modest effects on liver TG and insulin sensitivity. The magnitude of metformin–salicylate effect would be anticipated to be higher in insulin-resistant mouse models that have high rates of liver *de novo* lipogenesis, such as leptin deficient *ob/ob* mice or in mice fed a high fructose diet. Future studies investigating this possibility are warranted.

The therapeutic potential offered by combining low doses of metformin and salicylate is highlighted by the fact that the individual doses of these drugs required to fully activate liver AMPK may cause toxicity and/or intolerance [9,43]. Direct pharmaceutical remedies for NAFLD are also lacking, with weight loss being the best therapeutic strategy identified thus far. Whereas metformin consistently reduces liver fat in mice, small studies in humans utilizing the liver biopsy technique have yielded mixed results that suggest the effects of metformin alone may be relatively modest. It may be that larger clinical trials are needed to offset the large sample variance of the liver biopsy technique to clarify these findings. To the best of our knowledge, the role of salicylate-based drugs in regulating liver fat in humans has not been tested. Future clinical trials testing the effect of metformin and salicylate-based drugs on NAFLD using sensitive/direct methods of measuring liver fat and insulin sensitivity (NMR spectroscopy and hyperinsulinaemic–euglycaemic clamps respectively) are warranted.

In conclusion, the present study is the first to investigate the potential synergy of two widely used and well-tolerated drugs, metformin and salicylate, on AMPK activity, liver fatty acid

synthesis and insulin resistance. The therapeutic potential of the findings are highlighted by our observations showing that metformin combined with salicylate-based therapies (at serum concentrations achieved following the intake of an extra strength ASA) lower fatty acid synthesis in primary human hepatocytes and lower proinsulin levels in a large clinical cohort with dysglycaemia. These data support the use of salicylate-based drugs and metformin in combination to maximize activation of liver AMPK and suppress fatty acid synthesis. As elevated liver fatty acid synthesis is commonly observed in individuals with NAFLD and insulin resistance, combination therapy with salicylate and metformin may be effective for treating these prevalent conditions.

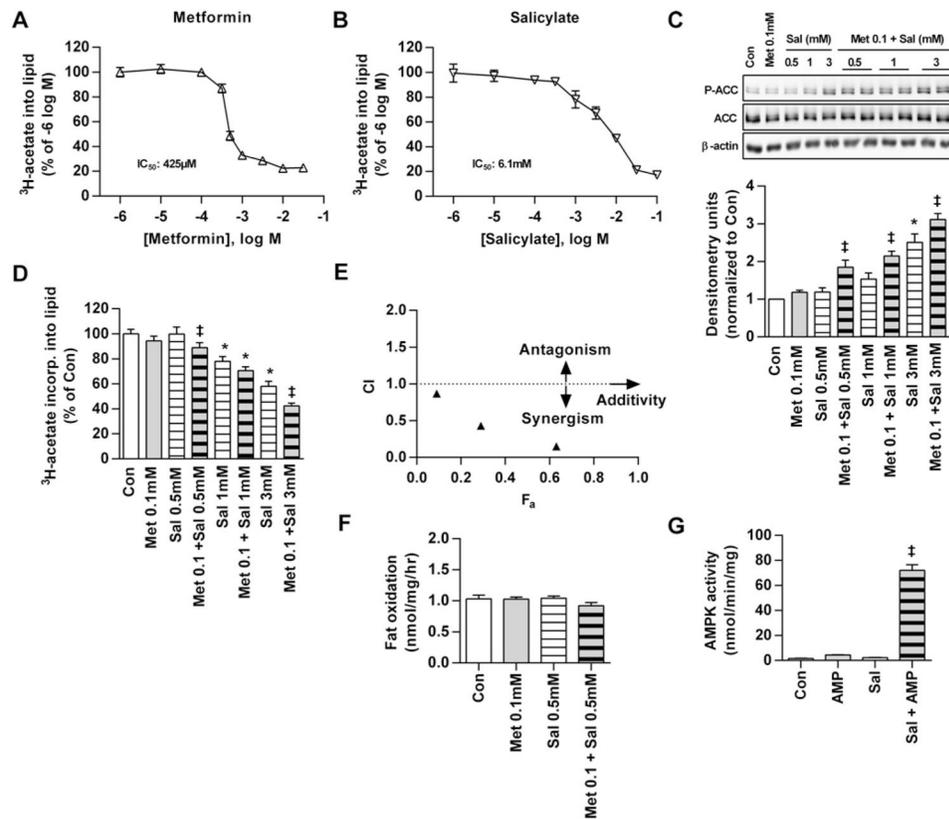

Figure 1. Metformin and salicylate synergistically activate AMPK and inhibit lipogenesis in primary mouse hepatocytes

Dose-dependent inhibition of *de novo* lipogenesis by (A) Met and (B) salicylate in mouse hepatocytes. (C) Ser^{79/212} P-ACC as a downstream target and marker of AMPK activation in primary mouse hepatocytes treated with no drug (Con), Met, salicylate (Sal) or Met + salicylate. (D) Inverse suppression of lipogenesis in mouse hepatocytes using the drug concentrations in (C). (E) CI compared with fractional effect inhibition (F_a) of lipogenesis in mouse hepatocytes treated with Met + salicylate (concentration ratio of 1:10 Met–salicylate) where CI > 1 indicates an antagonistic, CI = 1 additive or CI < 1 synergistic inhibition. Results represent at least two independent experiments performed in triplicate. (F) Fatty acid oxidation in mouse hepatocytes treated with no drug, low dose Met (0.1 mM), salicylate (0.5 mM) or both. Results from two independent experiments performed in triplicate. (G) Activation of AMPK by salicylate + AMP *in vitro* using purified, dephosphorylated AMPK $\alpha 1/\beta 1 \gamma 1$. Results were generated from four independent experiments. All densitometry is a ratio of phosphorylated to total protein. Data are means \pm S.E.M. except panel (E), which are –means only. * P < 0.05 compared with Con, ‡ P < 0.05 compared with both respective Met-only and Sal-only doses.

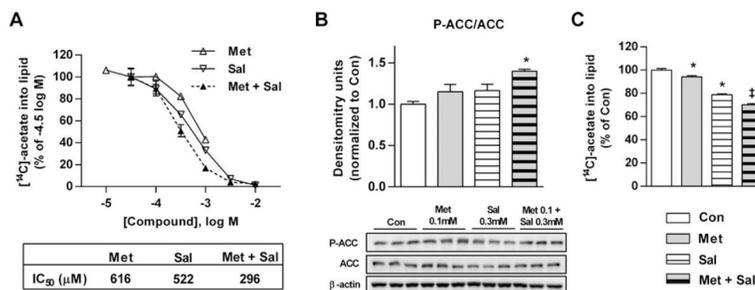

Figure 2. Metformin and salicylate synergistically activate AMPK and inhibit lipogenesis in primary human hepatocytes

(A) Dose-dependent inhibition of lipogenesis by Met, salicylate (Sal) or equimolar Met + salicylate (Met + Sal) in human hepatocytes. (B) Ser^{79/212} P-ACC as a downstream target and marker of AMPK activation in primary human hepatocytes treated with no drug (Con), 0.1 mM Met, 0.3 mM salicylate or Met + salicylate (0.1 and 0.3 mM respectively). (C) Suppression of lipogenesis in human primary hepatocytes treated with the drug conditions in (B). Results represent experiments from two donors performed in triplicate. All densitometry is a ratio of phosphorylated to total protein. Data are means ± S.E.M. **P* < 0.05 compared with Con, ‡*P* < 0.05 compared with both respective Met only and Sal only doses.

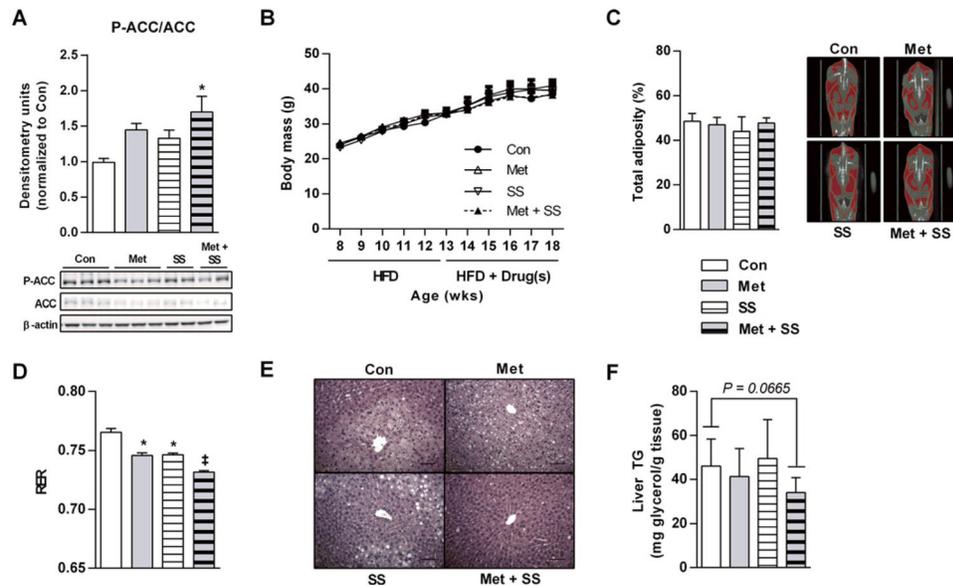

Figure 3. Metformin-salsalate combination treatment synergistically improves metabolic homeostasis and lowers liver lipids in HFD-fed mice

(A) P-ACC Ser^{79/212} (marker of AMPK activation; P-ACC) in clamped liver samples of C57bl/6 mice fed a 60 % HFD for 5 weeks followed by HFD with no drug (Con), 2.5 g/kg Met, 1 g/kg salsalate (SS) or Met and salsalate (Met + SS) for an additional 5 weeks. Densitometry is the ratio of phosphorylated to total protein. *n* = 5–8 mice per group. (B) Growth curves for mice on the diets indicated. *n* = 8 mice per group. (C) Percentage body adiposity by CT scan analysis. *n* = 8 mice per group. (D) Mean RER over a 24-h light-dark cycle. *n* = 4 mice per group. (E) Representative H & E staining of hepatic sections (scale bars, 100 μ m) illustrate liver lipid deposition and (F) total liver TG assayed as total liver glycerol. *n* = 8–12 mice per group. Legends are conserved across bar graph panels. All data are means \pm S.E.M. **P* < 0.05 compared with Con, ‡*P* < 0.01 compared with both respective Met-only and SS-only doses.

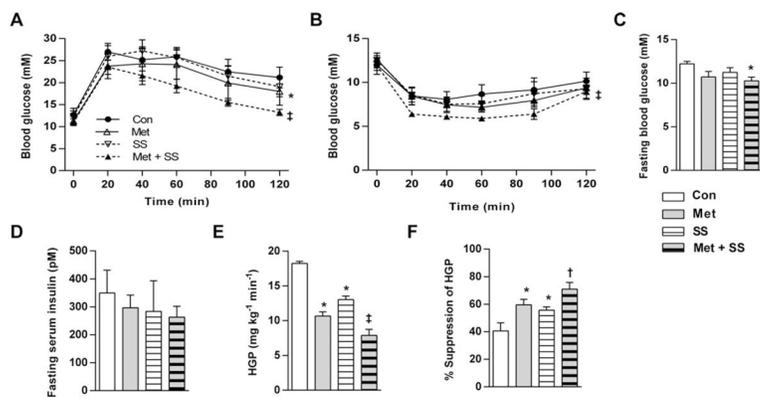

Figure 4. Met and salsalate synergistically improve liver insulin sensitivity in mice
 Intraperitoneal (A) GTT and (B) ITT for C57bl/6 mice fed a 60 % HFD for 5 weeks followed by HFD with no drug (Con), 2.5 g/kg Met, 1 g/kg salsalate (SS) or Met and salsalate (Met + SS) for an additional 5 weeks. (C) Whole blood glucose and (D) serum insulin concentrations following a 12-h fast. (E) HGP and (F) percentage suppression of hepatic glucose output during hyperinsulinaemic–euglycaemic clamps. Legends are conserved across line or bar graph panels. $n = 4-5$ mice per group for all measures. All data are means \pm S.E.M. * $P < 0.05$ compared with Con, ‡ $P < 0.01$ compared with both respective Met and SS only doses, † $P < 0.05$ compared with respective SS only.

Table 1

Metformin and ASA independently reduce proinsulin in humans with dysglycaemia

Variable	Model 1 (<i>n</i> = 8281)		Model 2 (<i>n</i> = 3381)	
	Estimate ± S.E.M.	<i>P</i> -value	Estimate ± S.E.M.	<i>P</i> -value
Intercept	0.3941 ± 0.0741	<0.0001	0.5253 ± 0.1166	<0.0001
Plasma insulin	0.4119 ± 0.0104	<0.0001	0.4325 ± 0.0166	<0.0001
FPG	0.0518 ± 0.0059	<0.0001	0.0665 ± 0.0088	<0.0001
HbA1c	0.1112 ± 0.0125	<0.0001	0.0755 ± 0.0194	<0.0001
Met	- 0.134 ± 0.023	<0.0001	N.D.	N.D.
ASA	- 0.049 ± 0.022	0.0247	N.D.	N.D.
Met + ASA	N.D.	N.D.	- 0.1801 ± 0.0331	<0.0001

Linear regression analyses of proinsulin levels were adjusted for age, sex, weight, plasma insulin, FPG and HbA1c levels. Analyses of metformin (Met) and ASA were adjusted for ASA and Met respectively. N.D., not determined.
