The measurement of visual ability in children with cerebral palsy: A systematic review

AIM To identify and evaluate measures of visual ability utilised with children with cerebral palsy (CP).

METHOD Eight databases were searched for measures of visual ability. Key selection criteria for measures were: (1) use with children with CP, and (2) focus of visual ability measurement at *Activities and Participation* domain of the International Classification of Functioning, Disability and Health (ICF). The Consensus-based Standards for the Selection of Measurement Instruments (COSMIN) Checklist was used to assess psychometric properties.

RESULTS From 6763 papers retrieved, 25 were relevant and 19 measures of visual ability were identified. Only ten measures were supported with evidence of validity or reliability. No discriminative measure analogous to existing CP functional classification systems was found. No outcome measure valid for evaluation of visual abilities of children with CP was found.

INTERPRETATION Vision impairment is recognised as relevant to the functioning of children with CP, however measurement of vision is most often focused at *Body Function* levels, e.g. visual acuity. Measuring visual abilities in the *Activities and Participation* domain is important in considering how a child with CP functions in vision-related activities. The lack of psychometrically strong measures for visual ability is a gap in current clinical practices and research.

WHAT THIS PAPER ADDS

1. A clear conceptual definition and framework for measuring visual ability is critical to furthering our understanding of the topic.
2. No valid evaluative measures of visual ability were identified.
3. There is no currently available measure of visual ability for children with CP analogous to existing CP functional classification systems.
INTRODUCTION

Cerebral palsy (CP) is a very prevalent physical disability in childhood\(^1\). Its definition has been revised to identify the possibility of secondary impairments including vision:

“Cerebral palsy describes a group of permanent disorders of the development of movement and posture, causing activity limitation, that are attributed to non-progressive disturbances that occurred in the developing fetal or infant brain. The motor disorders of cerebral palsy are often accompanied by disturbances of sensation, perception, cognition, communication, and behaviour, by epilepsy, and by secondary musculoskeletal problems” (Rosenbaum et al., 2007, p.9)\(^2\).

Impairments additional to the motor disorder contribute to the developmental and performance challenges faced by children with CP\(^3\), and evidence suggests that disturbances to vision can be especially challenging for children\(^4\). There is a growing body of literature reporting the relationship between vision impairments and various aspects of functioning for children with CP, including gross motor, communication, cognition, self-care and daily functioning skills\(^5\)–\(^11\).

Being able to describe the visual abilities of children with CP, and targeting interventions to promote visual abilities, are important areas for practice and research, and in order to establish efficacy for interventions targeting visual abilities or ‘useful vision’, valid and reliable measurement is required. The ‘Classification of Cerebral Palsy’\(^2\) specifies that accompanying impairments, including vision, should be classified as either present or absent, and that if present, the extent to which they interfere with the individual’s ability to function or participate in desired activities and roles should be described, but no specific guidelines are provided for this. It is recommended that vision be assessed, and that the standardized instruments for measuring vision function and impairment are accepted.

The challenge of terminology when measuring ‘vision’

The definition of visual impairment in the World Health Organisation’s (WHO) International Statistical Classification of Diseases and Related Health Problems (ICD-10)\(^12\) is based on “best corrected” vision. A level of vision impairment is obtained by measuring visual acuity with best possible refractive correction, and results are categories from ‘mild or no visual impairment’ (visual acuity equal to or better than 6/18) to ‘blindness’ (no light perception, light perception, or visual acuity worse than 3/60). A recent systematic review and meta-analysis on the rates of co-occurring impairments and functional limitations in children with CP utilised this definition in its finding that 1 in 10 children with CP has a severe visual impairment or is blind\(^3\). These findings suggest that impaired vision is a significant problem for some children with CP, however the authors of that review identified a lack of consistency among studies in the recording of information on vision impairments, and were consequently not able to include all vision impairment data in their analysis. Other ‘visual impairments’ included refractive errors, myopia, hypermetropia, astigmatism and strabismus, in addition to the reporting of children with ‘some impairment’ or ‘functional blindness’.

A definition or measurement of ‘visual impairment’ only describes the eye or visual functions being assessed, and these results, although valuable, do not specifically tell us how a child with CP functions in vision-related activities (their ‘visual ability’), particularly in the presence of other comorbidities such as gross motor limitations or cognitive impairments. Children with CP may be diagnosed with visual deficits that are of ocular (eye) or cerebral (brain) origin, or a combination of both, and recognition of vision impairment resulting from
damage to the brain is a rapidly growing area of research\textsuperscript{13}. Visual impairments that result from damage to the brain may be referred to as cortical, cerebral or neurological visual impairment. The visual abilities of a child can be impacted by impairments at any point along the primary visual pathway (eye, optic nerves, thalami, optic radiations, and primary visual cortices), in the visual association areas, or the oculomotor system\textsuperscript{14}.

Measurement of visual impairments, at the eye or brain level, does not directly provide information on functional limitations in daily life resulting from visual dysfunction, and does not provide information on the ‘positive aspects’ or ‘ability’ levels found in children with CP. While some children with CP may have a visual impairment that limits performance and restricts participation in daily life, for other children visual ability may be considered a strength.

The measurement of visual abilities is complex. Unlike visual acuity, where a count or measure of the finest detectable visual detail can be made, providing direct counts or observations of how vision is used in daily life is less straightforward; the assessor is confronted by parameters in addition to vision. Measurement of visual functioning requires conceptualisation of what constitutes the variable ‘visual ability’, in order for inferences to be made from observations\textsuperscript{15}. The distinction between commonly used terminologies such as ‘visual function’ and ‘functional vision’ must be clarified, as the measurement of these apparently similar terms can describe very different aspects of vision-related functioning\textsuperscript{16}. The absence of clearly defined measurement concepts is likely to lead to errors in measurement or in the interpretation of results, or both\textsuperscript{17}.

**A framework to describe the measurement of vision**

The International Classification of Functioning, Disability and Health (ICF) was published by WHO in 2001 as a framework for measuring health and disability\textsuperscript{18} (see Figure 1), and this was followed in 2006 by the release of the International Classification of Functioning, Disability and Health for Children and Youth (ICF-CY), designed to record the characteristics specific to the developing child. In this framework, ‘functioning’ is a term encompassing all body functions, activities and participation, and ‘disability’ is a term encompassing impairments, activity limitations and participation restrictions. The ability of a child to function is seen as a dynamic interaction between elements of these domains and is powerfully influenced by contextual factors including environmental barriers and facilitators to functioning, and personal factors. The ICF and ICF-CY provide a common language to describe functioning, and can serve as a connecting framework between assessments and interventions\textsuperscript{19}. The ICF framework is now frequently used in clinical and research practice\textsuperscript{20}, and there is a growing body of evidence reporting that impairment based measures can only provide limited information on functional abilities\textsuperscript{21, 22}.

The ICF framework can be used to define and describe the measurement of vision, and has been used by Colenbrander to differentiate between two types of vision\textsuperscript{23}. “Visual functions” describe how the eye functions, with deficits described as “visual impairments”, and these have been aligned with the *Body Functions and Structures* domain of the ICF. “Functional vision” describes how the child functions in vision-related activities, and this has been aligned with the *Activities and Participation* domain of the ICF. Functional vision is what the current authors term ‘visual ability’. Whilst in this non-hierarchical framework no domain is superior to another, and interaction between domains is highlighted, the ICF framework provides a
structure for considering where assessments and/or interventions are placed, and it defines the
type of information in each domain.

*Body Functions* are the “physiological functions of body systems (including psychological
functions)”, and *Body Structures* are “anatomical parts of the body such as organs, limbs and
their components”

Vision is most clearly described by the second chapter of the ICF Body Functions and Structures domain. The code b210 *Seeing functions* describes “sensory functions relating to sensing the presence of light and sensing the form, size, shape and colour of the visual stimuli”

This includes visual acuity, visual field functions, light sensitivity, colour vision, contrast sensitivity and the overall quality of the picture. This chapter also includes the functions of structures in and around the eye that facilitate seeing functions, including internal muscles (e.g. accommodation of the lens), external muscles (e.g. muscles to move the eyes for looking in different directions), and the eyelid (e.g. protective reflex). The codes for b210 *Seeing functions* and b2152 *Functions of external muscles of the eye* have recently been included in the ICF Core Set of categories most relevant to children and youth with CP

Vision involves more than seeing with the eyes, however, and another chapter from the ICF Body Functions and Structures domain is critical to how and what children see. The first chapter, b1 *Mental functions*, includes codes for orientation, intellect, attention, memory, psychomotor functions, perception (including visual perception and visuospatial perception), basic and higher-level cognition. These functions are all relevant and necessary to seeing, and creating useful vision. Vision may also be impaired by damage to structures related to the eye or structures of the brain.

Performance in vision-related activities is captured by the ICF Activities and Participation domain. *Activity* is “the execution of a task or action by an individual”, and *Participation* is “involvement in a life situation”. The domain chapters describe tasks, actions, and life situations where vision occurs: d1 *Learning and applying knowledge*, d2 *General tasks and demands*, d3 *Communication*, d4 *Mobility*, d5 *Self-care*, d6 *Domestic life*, d7 *Interpersonal interactions and relationships*, d8 *Major life areas* (including education), and d9 *Community, social and civic life*. There are three codes in the first chapter which are particularly relevant to using vision: d110 *Watching*, d160 *Focusing attention* and d161 *Directing attention*. An example of the assessment of vision that references the ICF-CY activity areas is the work of Hyvärinen, where four core areas of functioning have been identified for assessment: orientation/mobility, communication, activities of daily living, and sustained near vision tasks such as reading.

Visual abilities can be measured for different types of impairment (i.e. ocular or cerebral visual impairment), and the type or reason for the impairment is not the relevant factor. In this sense the measurement of vision can be descriptive of current abilities without the need to explain or interpret what is facilitating or inhibiting functioning. A valid measure of visual abilities will provide information about what a child with CP can do in vision-related activities; this is different from information that can be derived from results of measures of the eye/s or visual functions. Activity- and Participation-level measurement is influenced by Body Function parameters such as cognition, visual acuity and muscle tone; *Environmental Factors* such as wearing glasses to aid vision, or the presence and quality of lighting and distractions; and *Personal Factors* such as age and interest in the tasks at hand. This is
consistent with the ICF Framework’s depiction of these many factors as constituting a
dynamic biopsychosocial model, and a report of visual ability is likely to represent an
integrated assessment of ‘functioning’.

Two qualifiers or constructs within the ICF Activities and Participation domain can further
assist with interpreting abilities, including vision. Capacity describes an individual’s ‘best
performance’, and performance describes an individual’s ‘usual activity’. A measure of
visual ability that describes performance in vision-related activities would be considered to
provide the most useful information on daily functioning, whereas a measure that describes
visual capacity provides valuable information on how a child can perform given optimal
environmental conditions. Both forms of assessment were of interest in this review, because
interventions are often aimed at reducing the gap between these two related aspects of
functioning.

**Measurement of ‘visual ability’**
The definition of vision that describes a child’s functioning at the Activity and Participation
domain of the ICF is the focus of the current review, and what has previously been referred to
as ‘functional vision’ is hereafter defined as ‘visual ability’. The importance of visual abilities
to the functioning of children with CP, and the potential for providing clinical interventions at
the Activity and Participation level, together warrant a review of the availability of this type
of measure. We have addressed the complexity of defining visual ability for measurement and
intervention by applying the ICF framework to this area of practice. The primary objectives
of this systematic review were to identify what tools are currently available to classify and/or
measure the visual ability of children with CP; and to explore, among the identified tools, the
evidence for validity and reliability of visual ability measures in children with CP. The
broader research question of whether interventions can be provided to children with CP and
their families to improve activity performance (skills and abilities) in vision-related activities,
and/or minimise the impact of vision impairment (ocular or cerebral) on daily activities and
participation, cannot be answered in the absence of valid and reliable measures. This review
is one step towards addressing the visual abilities of children with cerebral palsy for clinicians
and researchers focusing on Activity and Participation level interventions.

**METHODS**
The methods used in this systematic review were designed according to the Preferred
Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA). The review
protocol was registered online in February 2014 with the International Prospective Register of
Systematic Reviews (Registration number CRD 42014006387) and can be accessed online at
http://www.crd.york.ac.uk/PROSPERO/prospero.asp.

**Eligibility criteria**
**Populations:** The review is focused on the measurement of visual ability in children (aged 0
to 18 years) with CP. A measure that has been developed for, or used with, children with a
disorder of movement and posture was considered a core requirement in the search for valid
and reliable measures of visual abilities for children with CP. Studies including children with
neurological impairments were eligible for inclusion when participant descriptions were
suggestive of CP, e.g. terms such as hemiplegia, hypoxic ischemic encephalopathy,
periventricular leukomalacia or intraventricular haemorrhage, brain injury or impairment in
the first five years of life, or where there was mention of a motor impairment (e.g. physical
disability). There was no limitation placed on what percentage of participants must be
children or have an eligible diagnosis.

Studies were excluded when participants were exclusively described by a diagnosis other than
CP (e.g. Down syndrome) or no participants were less than 18 years old. The paediatric focus
was important because of the variations in the activities and participation of adults compared
to children, and because the impairments seen in the adult population are different from those
seen in paediatric populations. Studies were also excluded if participants were described as
having only ocular or ‘low vision’ impairment, i.e. with no mention, or exclusion of, children
with physical or neurological disabilities.

Measures: Studies were sought that included measures of visual ability. Visual ability was
defined as “how someone performs in vision-related activities”16 and measures were
identified as addressing visual ability when the focus of the vision measurement was at the
Activities and Participation domain of the ICF. Any tool designed or described as
measuring ‘functional vision’ was included, and vision-specific subscales of broader tools
were included. Tools that assessed components of vision that focused only on the Body
Functions and Structures domain of the ICF (e.g. visual acuity, visual perception) are not
considered to be measuring visual ability as defined by this review and were excluded.
Measures designed for any purpose were eligible for inclusion i.e. descriptive,
discriminative, evaluative, and predictive measures30. A measure was eligible when
assessment resulted in a visual ability category, level or score. Descriptive records or
checklists were excluded, as were single item measures with only two categories (e.g.
‘functional vision’ and ‘no functional vision’). Measurement tools were not excluded on
the basis of their psychometric properties.

Publication types: Quantitative interventions, diagnostic, prediction or prognostic studies,
etiological assessments, frequency, instrumentation or psychometric studies were included.
Abstracts from conferences and unpublished studies were initially included, and further
information sought from the authors. Letters to the editor, and commentaries were excluded.
Only full papers written in English were included. There was no limit placed on the
publication dates of studies; it was anticipated that due to advances in technology, recent
studies might have a greater focus on the measurement of Body Function elements of vision
compared to the older approaches that relied on observation of performance.

Search
The search strategy was conducted in two steps. Step 1 involved the identification of visual
ability measures, and Step 2 searched for evidence of validity and reliability of the identified
measures. Searches were conducted in the following databases: Medline, CINAHL,
PsycINFO, ERIC, A+ Education, Embase, Scopus, and the Cochrane Library. An example of
the search strategy used in MEDLINE and modified for other databases is provided in
Appendix S1. Additionally, citations from papers and measures meeting the inclusion criteria
were tracked through Web of Knowledge, and hand searching of reference lists of retrieved
studies was carried out to ensure additional relevant references were identified. The searches
were conducted up to April 2015.

Step 1: Three key concepts were used to guide the first search strategy to identify measures of
visual ability: (i) measurement (e.g. classification, assessment), (ii) cerebral palsy (e.g. hemiplegia, brain injury), and (iii) vision (e.g. vision, blindness). Relevant terms and synonyms from the literature and medical subject headings (MeSH terms) and relevant terms from key literature (in title and abstract) were used to guide the search. Search results were limited to children.

Step 2: The names of the tools/measures found during the first search were used in a complementary search that aimed to identify additional papers with evidence of validity and/or reliability. The second search was conducted using the measure or author name as text words, and then combined with MeSH terms and keywords for validity and reliability. A decision was made not to seek psychometric evidence for measures containing visual subscales where these properties could not be interpreted separately from the whole measurement score.

**Study selection**
The first author screened all identified papers by title, and irrelevant papers were excluded. Two authors (BD and EF) then independently assessed the titles and abstracts of papers. Papers potentially meeting the inclusion criteria were retrieved in full text and reviewed independently by the same two authors. Consensus on the inclusion or exclusion of papers was reached using additional input through discussions with a third author (CI) when required. Where papers did not provide descriptive information on a tool, further searching was undertaken and/or authors of papers were contacted as required.

**Data collection process**
A data extraction sheet adapted from the CanChild Outcome Measures Rating Form was developed, piloted, and used to summarize information from published papers, manuals and correspondence with authors. Data extracted included information on papers reporting use of measures; general information on the tool (e.g. name of measure, authors); the focus of measure (ICF domains); clinical utility of the measure (e.g. instructions, format, time, training and cost); scale construction; standardization; reliability; and validity. The purpose of each measurement tool was determined by the review authors by looking at the aim, content and use of the measure, and by using established definitions. Measures were defined as describing details of what and how children function; discriminating variations of an issue to identify discrete levels of function; evaluating within-person change over time; and/or predicting some concurrent or future status. Tools were categorised as measuring visual ability at a performance or capacity level by analysing their aim and format of administration.

*Validity* refers to the accuracy of a measure. This review evaluated the content and construct validity of included measures. Special consideration was given to the development and content of measures, because in considering measurement of a concept like ‘vision’ it is important first to be sure that the measure is assessing the ‘right’ thing. As there is no gold standard for visual ability measurement, in this review whenever ‘criterion’ validity was mentioned as a psychometric property it was rated as ‘construct’ validity, as previously done by de Boer and colleagues. *Reliability* is the property of measure that shows that it is measuring something in a reproducible and consistent fashion. Internal consistency, inter-rater reliability, intra-rater reliability and test-retest reliability were considered in this review. Reliability correlation coefficients were described according to the CanChild Outcome Measures Rating Form (0.8 or above as ‘excellent’, 0.6 to 0.79 as ‘adequate’, and less than
0.6 as ‘poor’). Responsiveness is the ability of a measure to detect change within an individual over time.

Quality assessment
The Consensus-based Standards for the selection of health Measurement Instruments (COSMIN) checklist was used to evaluate the methodological quality of studies investigating aspects of reliability, validity, responsiveness and interpretability of identified measures of visual ability. Measurement properties were scored on a 4-point rating scale (poor, fair, good or excellent), and a final rating was determined from the lowest rating of any within the set of items measuring that psychometric property. Pairs of raters including BD plus one of EF, CI or SW completed the quality assessments independently, followed by discussion to reach consensus on a final rating. Consensus was reached for all ratings without involvement of a third author.

RESULTS
Search results
Search results and study selection processes that led to the identification of 19 included measures, are illustrated in Figure 2. Most excluded papers measured vision at the ICF Body Functions and Structures domain, i.e. visual acuity, visual field or visual perception. A list of excluded measures is available upon request from the lead author.

Included measures of visual ability
Table 1 summarizes the included measures of visual ability. Nine measures focused on visual performance and were typically questionnaires administered using caregiver report. Nine measures focused on visual capacity and were mostly administered test items or judgment-based therapist ratings. One measure addressed both visual performance and visual capacity. Although authors did not articulate the purpose of their measure using defined terminology, it was determined by the review authors that included measures had been developed and/or used to describe, discriminate, predict or evaluate visual ability, and some measures were intended for more than one purpose. The Atkinson Battery for Child Development for Examining Functional Vision (ABCDEFV) was the most commonly used measure, and the Health Utilities Index – Mark III (HUI-III) was the second most common, but most measures were described or utilised in only a single study. A list of studies utilising the measures is available in Appendix S2.

The identified measures utilised nominal (e.g. yes or no responses in the Preverbal Visual Assessment (PreViAs)) or ordinal levels of measurement. No measure used item weighting to calculate a total score, and the level of difficulty for individual visual ability items has not been established in any measure. The scores from measures were used to describe visual skills and abilities, to establish normal or estimated visual development, to describe or predict cerebral visual impairment, and to make recommendations about follow-up or further assessment and for intervention planning.

Psychometric properties of visual ability measures
Table 2 summarises the studies (n=11) that provided evidence about validity and reliability of the included measures. Studies included children with a range of motor and visual impairments (ocular and cerebral). Many of the included studies recruited participants from
sites providing services to children known or suspected to have visual impairments, such as from vision clinics. Validity and reliability results for the included measures are summarised in Table 3. Whilst construction of visual ability measures included comprehensive reviews of the literature and existing measures, combined with clinical experience of authors, there was no reported inclusion of children or primary caregivers in the selection of items for any visual ability measure. The Functional Visual Questionnaire, Visual Assessment Procedure – Capacity, Attention and Processing (VAP-CAP), and Visual Skills Inventory used factor analysis and principal components analysis to confirm dimensionality; however these factors were not incorporated into the scoring schema or used to aid interpretability of the measures. Internal consistency, test-retest, or inter-rater reliability were reported for 6 measures. Clinicians in reliability studies for the CVI Range and Erhardt Developmental Visual Assessment (EDVA) had undergone training programs in the administration and scoring of the measure, prior to testing. No measure reported intra-rater reliability, and there were no studies of responsiveness. Although 7 intervention studies were identified in the search, and 6 of these aimed to evaluate change in vision ability, none utilised an assessment tool with evidence to support validity for evaluative purposes.

The visual ability subscales identified from the Health Status Classification System – Preschool (HSCS-PS), HUI-III, and 15-Dimension Questionnaire do not allow interpretation of the vision scale separate from the other dimensions of health, and were therefore excluded from the analysis of psychometric information. Five measures had no available evidence for validity or reliability.

The methodological quality of ten studies reporting psychometric properties was evaluated using the COSMIN. The results of this analysis can be found in Table 4. No studies reported evidence for intra-rater reliability, measurement error, cultural validity or responsiveness on any measure. The overall quality of studies is primarily limited by small samples and lack of hypotheses to support construct validation. The statistical methods used in all studies were based on classical test theory. No study utilised an item response theory model to develop or evaluate the measure.

DISCUSSION
In this review, we sought measurement systems used to describe, discriminate, predict or evaluate the visual abilities of children with CP, and 19 measures were identified. The need to measure vision at a functional level has been identified previously, and this systematic review contributes an important contemporary overview of the field that could be used to inform future developments in alignment with modern approaches to measurement. The findings of this review suggest that visual ability measures are not in frequent use with children with CP and there is little evidence of ongoing validation of existing measures.

For this review the ICF was used as a conceptual framework to define the measurement of visual ability in relation to a child’s level of functioning in vision-related activities. This approach measures vision at the Activities and Participation domain, rather than measuring vision according to the Body Functions and Structures domain, where inferences need to be made about levels of functioning in daily activities. Despite the frequent use of the ICF in
rehabilitation research since its publication in 2001, only the authors of the Visual Function Questionnaire made reference to this framework.

The review identified some evidence of measures discriminating between levels of visual ability\textsuperscript{37,42} but there is currently no available measure to discriminate between levels of daily visual functioning analogous to existing functional classification systems for children with CP: the Gross Motor Function Classification System (GMFCS)\textsuperscript{65}, Manual Ability Classification System (MACS)\textsuperscript{66}, Communication Function Classification System (CFCS)\textsuperscript{67}, and Eating and Drinking Ability Classification System (EDACS)\textsuperscript{68}. Most available measures of visual ability are descriptive, and there are no measures validated for predictive or evaluative purposes.

**Current issues in visual ability measurement**

The results of this systematic review highlight a number of problems with the measurement of visual ability. First, a measure should be designed and validated for a specific purpose\textsuperscript{69}, but most measures included in this review did not clearly state the intended purpose of the ‘assessment’. Analysis of the included measures by the review authors suggests that most existing measures are meant to be descriptive tools.

Second, the items selected for a measure are important, and items in a descriptive measure should include all the characteristics that discriminate between individuals\textsuperscript{33}. The absence of children with CP, their primary caregivers and practitioners in the development of included measures makes it difficult to determine whether all domains of visual ability that are meaningful to the target population have been included. Furthermore, vision is a complex construct and it is important, in establishing validity, to determine whether only visual ability is being measured, or whether other factors are also making a significant contribution to the assessment of ability (e.g. motor skills, cognition or attention). Non-visual factors influence performance in vision-related activities, and therefore probably the measurement of visual ability. For example, the cognitive or learning skills of a child may influence their ability to see and recognise letters. Visual ability has been established as a uni-dimensional construct for measurement in other populations\textsuperscript{70,71}, and therefore it appears theoretically possible to achieve this in a measure suitable for children with CP. When determining the measurement construct it is also important not to be influenced by the name of a measure, but instead to look at the content and items\textsuperscript{32}. The ABCDEFV would appear to consist primarily of tests and items measuring vision at the Body Functions domain of the ICF, and although it includes “Functional Vision” in the battery name, it may not provide the type of information required by a practitioner interested in the direct assessment of daily visual functioning.

The third problem is that some measures included in this review utilised the common but problematic approach of adding raw nominal or ordinal scores to determine the ‘level’ of ability, and the relative contribution of each item to the total score was either not considered or not reported\textsuperscript{33,72}. This problem has previously been explained by Massof\textsuperscript{15}, and an example from the Functional Visual Questionnaire illustrates the issue. Two items from this measure, “Looks around when entering a room” and “Responds to facial expressions”, have the same ordered response alternatives that range from “never” to “often >75%” on a 5-point Likert scale. Whilst both items load on the same task-orientated visual skills factor, looking around a room is not likely to require the same level of visual
ability as recognising and responding to facial expressions. Averaging the scores on items such as these to produce a score would not provide a valid measure of daily visual performance, as the items themselves are not equivalent. In measurement systems such as this the score estimating a person’s visual ability depends on the choice of items. The scoring option of “not relevant”, or an equivalent option that results in no numerical score, was present in a number of the included measures and provides additional compromise to the measurement score. The degree to which one can assign any qualitative meaning to quantitative scores is also a major limitation of the visual ability measures in this review.

Finally, measures included in this review with evidence of construct validity relied heavily on correlations with, or discrimination from, Body Functions or Impairment-level measures. This was done in the absence of specific hypotheses for evidence of construct validity. The visual acuity and visual perceptual measures commonly used in these validation studies do not measure the same construct as visual ability or functioning in vision-related activities, and whilst positive correlations could be expected, a priori hypotheses that specify both the direction and the strength of the anticipated relationships need to be developed and tested to support construct validity.

**Implications for practice and research**
The focus of this systematic review should encourage practitioners and researchers to consider the possibility of visual impairments (ocular or cerebral) influencing the activities and participation of children with CP. Vision should be considered when gathering information from families, setting goals, and considering the focus for assessment and intervention. The results of this review can be used to guide visual ability measurement in practice and research. Clinical reasoning should include the consideration of purpose, content, and focus of available measures, and tools chosen must have proven validity and reliability for the intended purpose and population.

Based on the results of this review, five tools have some evidence to support their validity and reliability as descriptive performance measures of daily visual functioning. The CVI Range assesses visual functioning in children with CVI, the CVI Questionnaire screens for CVI, the Functional Visual Questionnaire assesses daily visual performance in children with CP who are difficult to assess, and the Visual Skills Inventory evaluates visual skills and responses in neurologically impaired children. The PreViAs assesses visual behaviour and visual cognitive abilities in infants, although there is only limited evidence of construct validity for children with motor impairments. Until psychometric evidence is available to support the use of these measures in clinical practice, questionnaires can be utilised to guide information-gathering on areas of daily functioning that are commonly limited by visual impairment. A useful finding of this review is the knowledge that measures utilising questionnaires to gather information from parents result in information about a child’s daily performance, whilst clinician-administered measures provide information on best performance. There are also six tools with some psychometric evidence to support their use as descriptive measures of visual capacity (best performance).

There are currently no valid measures of visual ability for predictive or evaluative purposes. In the absence of valid and reliable evaluative measures, it is impossible to quantify whether interventions are without efficacy or whether we are simply unable to detect clinically...
important change. The current lack of evidence about interventions to improve the visual abilities of children with cerebral palsy adds urgency to the need for valid and reliable measures of visual abilities\cite{73, 74, 75}. Until valid and reliable visual ability measures are developed, it is recommended that practitioners consider utilising individualised goal-based measures such as the Canadian Occupational Performance Measure\cite{76} or Goal Attainment Scaling\cite{77} for the evaluation of interventions related to specific visual ability goals. These outcome measures have established validity, reliability, and are sensitive to change\cite{78}.

**Future directions for research**

Several directions for future research have been highlighted by this review. First, further analysis of the conceptual foundations of identified measures is essential, because clinicians and researchers must know whether they are measuring visual ability or some other construct. Linking items from measures to specific chapters and codes of the ICF using Cieza’s established linking rules\cite{79} will clarify which content and tools focus at an item level on measuring visual ability. Preliminary analysis of the content of included visual ability measures at a subscale level identifies frequently occurring constructs such as attention, communication and social interactions, visual processing, visual motor coordination, and the role of the environment and other senses (e.g. touch, listening). Further analysis of content may also provide insight into whether vision measured within the context of functional activities are measuring activity level performance, or whether scoring occurs at the Body Function level\cite{22}.

Second, the review results also suggest the need for a classification system to describe ‘levels’ of visual functioning in children with CP analogous to existing functional classification systems e.g. the MACS\cite{66}. Third, future research should seek confirmation from children with CP and their families that all characteristics that discriminate levels of visual functioning, and those that are meaningful, have been identified. Fourth, there is a need for evaluative measures of visual ability for use in intervention studies and clinical practice. Both parents and practitioners are likely to have valuable insights on what is functionally important in the daily lives of children with CP, and which abilities are likely to change following intervention\cite{30}. Fifth, the dimensionality of a measure of visual ability needs to be investigated to confirm whether measurement of this construct can be achieved in a single scale. Sixth, a hierarchy for visual abilities should be established using methods such as item response theory, and interval level measurement. And finally, systems for the qualitative interpretation of scores must also be developed for families, practitioners and researchers to make use of quantitative scores.

To move this field of research forward, future studies need to consider the spectrum of children diagnosed with CP, including age and functional levels. Researchers are encouraged to select and describe participants using the GMFCS, MACS, and CFCS. A limiting factor for a number of the included measures in this review is the focus on subsets of the CP population, or not all measurement items being relevant for all children. Children with CP present with a diverse range of functional abilities, including varied levels of motor and cognitive abilities. It is also suggested that in the future as a complement to visual diagnoses, measures of visual ability should focus not only on the underlying reasons for impairment (i.e. CVI), but rather on levels of visual ability in daily activities. This approach of focusing on ability has been well established in other functional measurement systems for children with CP\cite{27}. This review also highlights the importance of good quality psychometric studies. An increasing awareness
and use of checklists such as the COSMIN rating system would help in designing and reporting future high quality studies in support of measurement systems.

Benefits from focusing on the functional impact of visual impairments are likely to include increased focus on and monitoring of the development of visual abilities; increased analysis of how vision impacts activity performance; and increased focus on visual abilities as facilitators or barriers to participation. Interventions will be developed to target visual abilities, and levels of visual ability may be able to guide the selection of management options. Consistency in terminology will increase the clarity of communication about vision and visual abilities, and enable comparisons across CP populations and research studies. Research into other areas of functioning (e.g. manual abilities) will also benefit from the ability to stratify participants by level of visual ability. Establishing the validity of visual ability measurement systems for predictive purposes will also assist services and policy makers with planning for future intervention and care needs.

**Limitations**
There are some limitations to this review. Firstly, studies not published in English were excluded, so some measures of visual ability may have been missed. Secondly, this review focused specifically on the identification of measurement in children with CP. Whilst this criterion was established because the primary disability of this population is a movement or posture impairment that is likely to need consideration in item selection, it is acknowledged that measures developed for use with children without physical impairments might also provide valuable information. Future research may include validation studies of other existing measures for children with CP (e.g. CVI Inventory). Thirdly, this review has not reported on clinical utility of available measures, focusing instead on measurement properties. Finally, although inclusion criteria focused this review on the identification of visual measurement at the Activities and Participation level of the ICF, the extent to which the selected measures met this aim requires further assessment, as some included measures appear to contain both Body Function and Activities and Participation level items. Body Function items are likely to assess different aspects of visual ability from items related to Activities and Participation. Whilst analysis of visual ability measures at an item level was beyond the scope of this review, further exploration may contribute to our understanding of the visual ability construct in children with cerebral palsy, and provide evidence on the usefulness of existing visual ability measures at an item level.

**CONCLUSION**
This systematic review applied the ICF framework to define, identify and evaluate currently available measures of visual ability for children with CP. Results show that while visual ability is being measured, there is no consensus on what visual abilities should be measured, or how, and there is generally a lack of strong psychometric properties. We are currently unable to discriminate the range of visual abilities across the CP population, and there is no valid method to evaluate interventions aiming to change visual ability. Whilst measurement in the Body Functions and Structures domain, such as visual acuity tests for measuring eye function, and cognitive test for measuring perception of vision, will continue to be important, it is hoped that the ICF framework can be utilised by researchers, practitioners, and policy administrators to understand the inadequacy of relying on impairment measures to describe levels of functioning and disability. In the future vision measurement should occur at both the Body Function and Activity and Participation levels of the ICF.
The results of this review can be used to develop the way visual impairment, and daily functioning, are considered, and to guide future development of valid and reliable visual ability measurement in both new and existing tools. Whilst not an easy task, appropriately developed and psychometrically sound measures would have tremendous clinical and practical utility for children with CP because they would promote understanding of the impact visual impairment (ocular or cerebral) can have on daily functioning and other areas of development, and facilitate the development of future interventions targeted at visual abilities.
